Course and Treatment of Chronic Obstructive Pulmonary Disease

M. Bradley Drummond
Robert A. Wise

INTRODUCTION

In past decades, the treatment of chronic obstructive pulmonary disease (COPD) has been approached by many physicians and patients alike with a nihilistic attitude, assuming that the disease was progressive, incurable, and untreatable. More recently, as our understanding of the clinical epidemiology and value of therapy of COPD has improved, this attitude has changed. Physicians have come to approach COPD in the same way as other chronic diseases with goals of improving quality of life, functional capacity, and prolonged survival. With a comprehensive approach to treatment, COPD is compatible with prolonged survival, good quality of life, and independent functional status for many who have this illness. The purpose of this chapter is to summarize the current understanding of the course of COPD and best approaches to treatment.

OVERVIEW OF COPD

COPD is a disorder that is characterized by slow emptying of the lung during a forced expiration. In practice, this is measured as the forced expiratory volume in 1 second/forced vital capacity (FEV_1/FVC) ratio, and the arbitrary definition of airflow obstruction is generally taken to be an FEV_1/FVC ratio lower than 0.70.[1] Because the rate of emptying of the lung falls with advancing age, many elderly individuals demonstrate airflow obstruction even in the absence of a clinical diagnosis of COPD. For this reason, an alternative criterion to define airflow obstruction incorporates lower limit of normal thresholds instead of the fixed ratio criteria.[2] Several disorders cause chronic airflow obstruction—long-standing asthma, cystic fibrosis, bronchiectasis, bronchiolitis obliterans, lymphangioleiomyomatosis, panbronchiolitis, silicosis, Sjögren syndrome, and diffuse interstitial processes such as eosinophilic granuloma and sarcoidosis. The diagnosis of COPD is usually limited to individuals who have chronic airflow obstruction associated with tobacco smoke or some other noxious inhalant, and it is usually not difficult to distinguish it from other causes of chronic airflow obstruction. The most common disorders associated with COPD are emphysema and chronic bronchitis. *Emphysema* is defined anatomically by airspace enlargement due to disappearance of alveolar septae (Chapter 37). This leads to the characteristic loss of elastic recoil, which, in turn, causes slowing of airflow from the lungs, hyperinflation, and air trapping. *Chronic bronchitis* is characterized by chronic cough and sputum production, which is present in about one out of three people with early COPD. Chronic cough and sputum production in cigarette smokers is often, but not always, associated with chronic airflow obstruction. When chronic mucus hypersecretion is associated with airflow obstruction, it is often called *chronic obstructive bronchitis*. Although people with nonobstructive mucus hypersecretion (nonobstructive chronic bronchitis) have a greater risk for acute respiratory illness, most such individuals will not progress to airflow limitation, and therefore, the term "pre-COPD" should be avoided.[3] It is unknown whether maintenance treatment of nonobstructive chronic bronchitis is beneficial. The anatomic correlates of chronic bronchitis are mucus gland hyperplasia and goblet cell metaplasia in large- and medium-sized airways.[4] Patients with COPD also have small- and medium-sized airway involvement with inflammation, narrowing, tortuosity, mucus plugging, and fibrosis that contributes to the airflow limitation. As the disease evolves, there is obliteration of small airways. Some patients with a long-standing history of asthma develop airflow obstruction that is not completely reversible, episodes of cough and wheeze, and chronic sputum production. These individuals are often classified as having *chronic asthmatic bronchitis* and have a better prognosis for survival than those with tobacco-related COPD.

NATURAL HISTORY OF COPD

COPD occurs in middle age and later because of the age-related decline in lung function over time. Typically, peak lung function occurs during the third or fourth decades of life. Healthy nonsmoking adults lose FEV_1 at a rate of 30 mL/year, thought to be the consequence of the aging-related loss of elastic recoil of the lung. Persons who develop COPD may start in early adulthood with low levels of lung function or with a normal rate of decline or may have normal young adult lung function and have increased rates of decline.[5,6] Studies of patients with COPD show an average annual decline in FEV_1 of 45 to 69 mL/year (Fig. 40-1A). However, there may be considerable heterogeneity between patients and over time.[7,8] This leads to the insidious loss of ventilatory reserve capacity that often is asymptomatic and unrecognized by patients and physicians alike. Chronic bronchitis may be dismissed as an innocent "smoker's cough" because patients fail to understand that it is abnormal to produce daily sputum. As ventilatory reserve decreases, people with mild COPD tend to limit strenuous activities, so breathlessness with activities of daily living is not ordinarily an early symptom of the disease. When the ventilatory reserve decreases to the extent that mild exertion such as climbing stairs, bed making, or carrying groceries is limited, patients tend to seek medical advice. In some cases, the first clinical presentation of disease is an acute episode of bronchospasm, dyspnea, or even respiratory failure in association with a respiratory infection or exposure to respiratory irritants. Thus, the onset of COPD may appear precipitous even though it is the cumulative result of decades of progression.

People who discontinue smoking with mild to moderate degrees of airflow obstruction cease the rapid decline in FEV_1 and have better survival (Fig. 40-1B).[9,10,11] The improvement in survival depends largely upon the stage of disease. Persons who quit smoking with earlier disease have better outcomes compared with those who continue to smoke or those who quit smoking later in the disease. Once the disease is advanced, the inflammatory response may persist, and the proportional loss of lung function tends to progress. Because there are many years of asymptomatic decline in lung function, it is possible to diagnose COPD with forced expiratory spirometry before the disease is apparent and implement aggressive smoking intervention programs. There is a consensus that smokers with respiratory symptoms should be tested for COPD with spirometry. However, there is debate whether it is of value to screen for COPD among all cigarette smokers.[12] Opponents of using spirometry for case-finding argue that the finding of a normal test would not alter physician behavior because all smokers should be encouraged to quit. It has also been argued that a normal spirometry test might provide a false sense of complacency for active smokers. Those who support the use of spirometry for COPD case-finding argue that early detection and aggressive smoking intervention have been

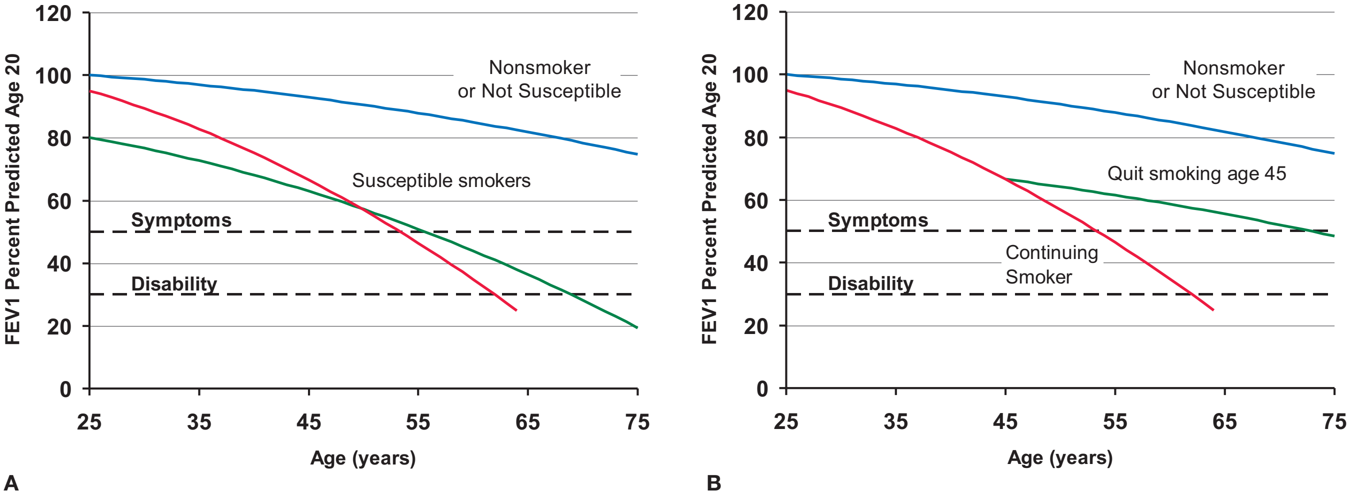

Figure 40-1 **A.** The natural history of COPD is presented for three hypothetical individuals. Pulmonary function is plotted as the percent of predicted lung function for a young adult who has attained maximal lung growth. Those who do not smoke or are not susceptible to cigarette smoke typically lose about 25% of their young adult lung function throughout life. Individuals are susceptible to the adverse effects of smoking because of increased decline of lung function, or low lung function in young adult life. Although the abnormality of lung function is detectable for many years, symptoms do not develop until there is loss of approximately 50% of lung function *(upper dashed line)*, which occurs in middle age or later. If the disease progresses, it may lead to substantial disability within a decade of the onset of symptoms *(lower dashed line)*. **B.** The natural history of COPD is displayed for a hypothetical continuing smoker, and an individual who quit smoking at age 45. The axes are identical to those in (**A**). If an individual cease smoking in the asymptomatic phase of COPD, the rate of decline of lung function reverts toward normal. In this example, the detection of abnormal lung function and cessation of smoking has a substantial effect of delaying the onset of respiratory symptoms. This plot is modified from the work of Fletcher and Peto and is commonly referred to as Fletcher-Peto curves.

proven to halt disease progression and improve survival, and the finding of abnormal spirometry may encourage patients and healthcare professionals to be more aggressive with smoking cessation. Moreover, some evidence points to the benefits of drug therapy in terms of lung function decline and survival in patients with mild to moderate airflow obstruction.[13–15]

With the progression of COPD comes progressive exercise limitation.[16] This is due to the increased work of breathing as ventilation increases with exercise. With increased respiratory rate, patients develop dynamic hyperinflation—a condition in which the end-expiratory lung volume does not return to the static end-expiratory volume of functional residual capacity (FRC). The hyperinflation that occurs causes increased work of breathing and exacerbates dyspnea. An indicator of dynamic hyperinflation is the inspiratory capacity (IC), which progressively falls with increasing ventilation. Measures that reduce dynamic hyperinflation, increasing IC, can improve exercise capacity. These include alterations in breathing pattern, oxygen supplementation, and use of inhaled bronchodilators. Similarly, episodes of anxiety can lead to tachypnea that induces dynamic hyperinflation and exacerbates the experience of dyspnea at rest. These episodes can often be minimized by explanation of the phenomenon to the patient and caregivers as well as judicious use of self-relaxation, pursed-lip breathing, and anxiolytics.

As COPD progresses, ventilation–perfusion inhomogeneity causes an increase in the alveolar–arterial oxygen difference. Eventually, alveolar hypoxemia leads to pulmonary hypertension, which manifests as cor pulmonale. The alveolar hypoxemia may be compounded by alveolar hypoventilation—manifested by arterial hypercapnia. Physical findings indicative of cor pulmonale are venous engorgement, edema, and physical findings of pulmonary hypertension and right ventricular failure including elevated venous pressure, accentuated pulmonic second heart sound, right ventricular heave, tricuspid regurgitation murmur, hepatojugular reflux, and ascites. Chest imaging shows central enlargement of the pulmonary arteries. Once cor pulmonale is clinically apparent, survival is markedly reduced in proportion to the impairment of functional capacity.

Patients with advanced COPD may restrict their activities to a bed-and-chair lifestyle because of severe exercise incapacitation. This limitation can lead to social isolation, depression, and skeletal muscle deconditioning, which, in turn, further restrict activity and impair quality of life. Protein and calorie malnutrition occur as the consequence of impaired nutritional intake caused by dyspnea.[17] Malnutrition is augmented by increased metabolic demands caused by increased basal oxygen consumption, inefficient skeletal muscle oxygen utilization, and cachexia-producing cytokines such as tumor necrosis factor α (TNF-α).[18]

DIAGNOSIS OF COPD

Physical examination and chest imaging are insensitive methods for diagnosis of COPD. Physical findings of hyperinflated lungs such as low-lying diaphragm, decreased breath sounds, and hyperresonant chest percussion are highly specific for COPD, but usually only in advanced disease.[19,20] One study has suggested that a distance between the thyroid cartilage and the sternal notch less than 4 cm in a smoker older than age 45 is highly indicative of the presence of COPD.[21] Clubbing of the fingers is rare in COPD and, if present, suggests another diagnosis such as bronchiectasis, asbestosis, or lung cancer. High-resolution computed tomography (HRCT) of the lung is useful in establishing the presence of emphysema. Quantitative analysis of HRCT is a useful technique for early detection of emphysema but is not widely available in clinical practice at this time. α_1-Antitrypsin deficiency is an uncommon, but not rare, condition associated with premature emphysema. Table 40-1 lists conditions that suggest the presence of α1-antitrypsin deficiency. Some experts advise that all patients with emphysema or fixed airflow obstruction should be tested for α_1-antitrypsin because treatments are available for those with the most severe form of deficiency.[22,23] HIV/AIDS also is associated with premature emphysema and accelerated lung

TABLE 40-1 Conditions Suggesting α1-Antitrypsin Deficiency

Early-onset emphysema (age under 45 years)
Emphysema in a nonsmoker
Emphysema predominantly in lung bases (panacinar)
Necrotizing panniculitis (Weber–Christian disease)
c-ANCA positive vasculitis (e.g., granulomatosis with polyangiitis)
Family history of early-onset emphysema or non–smoking-related emphysema
Family history of cirrhosis
Bronchiectasis without other etiology

function decline, and screening for HIV should be performed for persons with emphysema and HIV risk factors such as intravenous drug use or high-risk sexual activity.[24,25]

The diagnosis of COPD, classification of its severity, and progression of the disease can be monitored with spirometry, a simple, noninvasive, and inexpensive test. The FEV$_1$/FVC ratio, reflecting the rate of emptying of the lung, is used to define the presence of an obstructive ventilatory defect, commonly defined as a ratio less than 0.70 or below the lower limit of normal. Once airflow obstruction is established, the severity of the airflow limitation is classified by the reduction of FEV$_1$ compared with a healthy reference population. Lung volume measurements, by plethysmography, helium dilution, nitrogen washout, or single-breath methods typically show hyperinflation (elevated TLC) and air trapping (elevated residual volume [RV]), and thus are useful to exclude restrictive lung diseases. The carbon monoxide diffusing capacity (DL$_{CO}$) is an indicator of emphysema and is an independent predictor of mortality.

COPD is categorized based on the severity of airflow obstruction, presence of symptoms, propensity for exacerbations, and radiographic appearance. Airflow obstruction is based on spirometry (Table 40-2); symptoms are elicited with standard questionnaires such as the COPD Assessment Test (CAT)[26,27] and mMRC dyspnea scale (Table 40-3); exacerbation risk is determined primarily by a history of previous exacerbations requiring treatment;[28] and emphysema is quantified by CT.[29,30]

PROGNOSIS OF COPD

The prognosis in COPD may vary widely. Physicians are poor prognosticators of survival in COPD.[22] In part, this is because the disease is one of widely varying rates of progression, and in part, this is because death is often due to susceptibility to intercurrent illness and other smoking-related illness such as lung cancer rather than progressive respiratory failure. Recent studies have demonstrated heterogeneity in lung function decline, with some patients with COPD having little or no decline in FEV$_1$ over time.[7,8]

TABLE 40-3 Modified Medical Research Council Dyspnea Scale (mMRC Scale)

Grade	Description
0	Not troubled with breathlessness except with strenuous exercise
1	Troubled by shortness of breath when hurrying on the level or walking up a slight hill
2	Walks slower than people of the same age on the level because of breathlessness or has to stop for breath when walking at own pace on the level
3	Stops for breath after walking about 100 yards or after a few minutes on the level
4	Too breathless to leave the house or breathless when dressing or undressing

Data from Celli BR, MacNee W. ATS/ERS Task Force. Standards for the diagnosis and treatment of patients with COPD: A summary of the ATS/ERS position paper. Eur Respir J. 2004;23(6):932–946.

Several factors have been identified that predict poor survival in COPD. These include low FEV$_1$, low inspiratory capacity, active smoking status, hypoxemia, poor nutrition, the presence of cor pulmonale, resting tachycardia, low exercise capacity, severe dyspnea, poor health-related quality of life, anemia, frequent or severe exacerbations, comorbid illnesses, and low D$_{CO}$.[31,32] Patients with moderate to very severe airflow limitation and a history of exacerbations have about 3% annual mortality if treated with bronchodilators alone. All-cause mortality is reduced by about 40% if inhaled corticosteroids are added to the treatment regimen.[33,34] If a patient reports that they are unable to walk 100 m without stopping because of breathlessness, the 5-year survival is only 30%.[35] A multidimensional prognostic index that takes into account several indicators of COPD prognosis is the BODE index (*b*ody mass index [BMI], *o*bstructive ventilatory defect severity, *d*yspnea severity, and *e*xercise capacity).[36,37] See Table 40-4 for calculation of the BODE prognostic score. The components are derived from measures of the BMI (weight in kg/height m^2), FEV$_1$ percent predicted, and the modified Medical Research Council dyspnea score (Table 40-3). A BODE score greater than 7 is associated with a 30% 2-year mortality, whereas a score of 5 to 6 is associated with 15% 2-year mortality. If the BODE score is less than 5, the 2-year mortality is less than

TABLE 40-2 Classification of Severity of Airflow Limitation in COPD

Ventilatory Impairment	Characteristics
I Mild COPD[a]	FEV$_1$ $\geq$80% predicted
II Moderate COPD[a]	FEV$_1$ 50%–79% predicted
III Severe COPD[a]	FEV$_1$ 30%–49% predicted
IV Very severe COPD[a]	FEV$_1$ $<$30% predicted or $<$50% predicted with room air Pa$_{O_2}$ $<$60 mm Hg (8.0 kPa)

10%. In settings where the 6-minute walk test is not available, the ADO index (*a*ge, *d*yspnea, and *o*bstruction) also provides useful prognostic information (Table 40-5).[38] The ADO index ranges from 0 to 10 points, with each point increase in the index associated with a 42% marginal increase in odds of death at 3 years for patients with long-standing and severe COPD.

TREATMENT OF STABLE COPD

The goals of treatment of COPD are to prevent progression and complications of the disease, relieve symptoms, improve exercise capacity, improve quality of life, prevent and treat exacerbations, and improve survival.

Education

The diagnosis of COPD can be a life-changing event for people, so understanding the nature and prognosis of the disease is an important and underemphasized aspect of care. There is a wide divergence of understanding of the implications of having COPD, and many patients do not understand that COPD comprises both the diagnoses of emphysema and chronic bronchitis. Table 40-6 lists topics that should be discussed with COPD patients. It is neither possible nor effective to cover all these topics in a single session, so several sessions with repetition and expansion of the educational messages are necessary. Supplemental written materials or referral to a health educator also is necessary for many patients. Local and national volunteer health organizations provide useful educational materials and group educational sessions (e.g., www.copdfoundation.org, www.lung.org). Special counseling is needed for patients with α_1-antitrypsin deficiency and their family members to determine whether genetic testing is necessary or desired. In patients with advanced disease, discussions about end-of-life planning and advance directives regarding life support are often welcomed by patients and initiate discussions between the patient and family. Patients should be encouraged to discuss information that they obtain from newspapers or the Internet, as some may be instructive, but others are incorrect. Physicians should be prepared to deal with patients' sense of guilt, as many view COPD as a self-induced disease. Caregivers need to address the reality that COPD is often stigmatized by patients, their families, and other healthcare providers. The physician should let the patient understand that nicotine dependence is a strong physical addiction and difficulty quitting smoking is not a measure of moral weakness or lack of will. The general message provided should be realistic, but positive. Current treatments for COPD can improve quality of life, improve activity levels, maintain social interactions, and reduce the frequency of complications.

TABLE 40-6 Patient Education Topics for Management of COPD

Risk factors for COPD
Smoking cessation advice and instruction
Reduction of noxious environmental exposures
Immunization for influenza and pneumococcus
Respiratory hygiene and avoidance of infections
Nature and prognosis of COPD
Indications, dose, benefits, and adverse effects of medications
Proper inhaler and nebulizer use
Strategies to improve adherence with prescribed treatment
Pacing, arm support, pursed lip breathing, and other strategies to minimize dyspnea
Importance of regular exercise and social interaction
Options for pulmonary rehabilitation programs
Recognition and early treatment of exacerbations
Indications for and proper use of supplemental oxygen
Options for surgical management if indicated
Advance directives for end-of-life care

Prevention of COPD Progression and Complications

Presently, there are no proven treatments that prevent the progression of COPD in patients who continue to smoke cigarettes. *Smoking cessation*, however, does prevent the excessive decline in lung function and should be a primary goal for physicians caring for COPD patients. Patients with mild or moderate COPD may not know that they have underlying lung disease that can be halted by smoking cessation or may adopt a fatalistic attitude that it is too late for help. Even severely impaired patients who are dyspneic at rest or use continuous oxygen may continue to smoke cigarettes or relapse after quitting. A smoking history should be obtained at each patient encounter because many patients fail to volunteer the extent of their smoking or report a smoking relapse following cessation. In patients who do smoke, achieving cessation should be a primary and persistent goal of treatment.[39] Approaches to smoking cessation are given in detail in Chapter 41. For patients who do smoke, a direct, unambiguous, and personalized smoking cessation message should be given by the physician. The message should emphasize the harm of continued smoking, the benefits of cessation in terms of activities that are meaningful for the individual, and the understanding that smoking cessation is a realistic and achievable goal. Techniques of motivational interviewing are readily learned and are effective in changing health behaviors.[40] Assistance with pharmacologic adjuncts such as nicotine replacement therapy, varenicline, or bupropion and referral to smoking cessation groups should be offered. Follow-up of smoking status and repeated smoking cessation messages should be performed at each encounter.

Exposure to respiratory irritants should be avoided in the workplace as well as the home. Although heavy occupational dust exposure rarely is the primary cause of COPD, exposure to dusty occupational jobs in smokers can increase the lung function deterioration from smoking and increase symptoms of cough and sputum.[41] In developing countries, heavy exposure to particulates from burning of biomass fuels is associated with COPD, even in the absence of cigarette smoking.[42,43] Efforts to improve indoor air quality may be effective in reducing symptoms and disease progression. Respiratory protective equipment should be worn by patients with COPD exposed to heavy dust concentrations. There is no level of FEV$_1$ that absolutely prohibits the use of respiratory protective equipment, but patients with COPD often experience untoward breathlessness with these masks because of the increased dead space and increased inspiratory resistance. Thus, many patients with COPD need to change their work environment if they cannot tolerate protective devices. If COPD is complicated by allergy or overlaps with allergic asthma, environmental control measures should be instituted to the extent that these strategies are helpful. Smoking of marijuana and cocaine may cause airway irritation, and although there is no convincing evidence that they contribute to progression of COPD, their use ought to be discouraged. Occasionally, heavy daily marijuana smokers will develop giant bullous emphysema, which has been called "marijuana lung," but the causality remains to be established.[44,45]

Pneumococcal vaccination is recommended and has been shown to reduce community-acquired pneumonia and possibly reduce exacerbation frequency in COPD.[46] Annual inactivated *influenza immunization* can prevent subsequent exacerbations due to influenza infections.[47] High-potency influenza immunization is recommended for older patients who may have an impaired immune response to the vaccine. During influenza epidemics, the use of neuraminidase inhibitors such as oseltamivir or RNA polymerase inhibitors such as baloxovir can minimize severity of infection if taken within 48 h of onset of illness and are useful against both influenza A and B and may limit the spread of infection. Peramivir, an injectable form of neuraminidase inhibitor, is now available for treatment of individuals with respiratory failure.

Replacement therapy with α_1*-antitrypsin* should be considered for those individuals with severe deficiency. Observational studies suggest that individuals with moderate degrees of impairment (FEV_1 35%–65% predicted) appear to benefit most in terms of preservation of lung function and improved survival.[48] Studies of HRCT progression of emphysema indicate a measurable benefit across a wider range of lung function.[49,50] The human plasma–derived preparation of α_1-antitrypsin is administered intravenously in a dose of 60 mg/kg weekly. Replacement treatment is derived from pooled human plasma, so immunization for hepatitis A and B is suggested. IgA deficiency may increase the risk of allergic reactions and therefore some authorities recommend testing for IgA levels before initiating therapy.

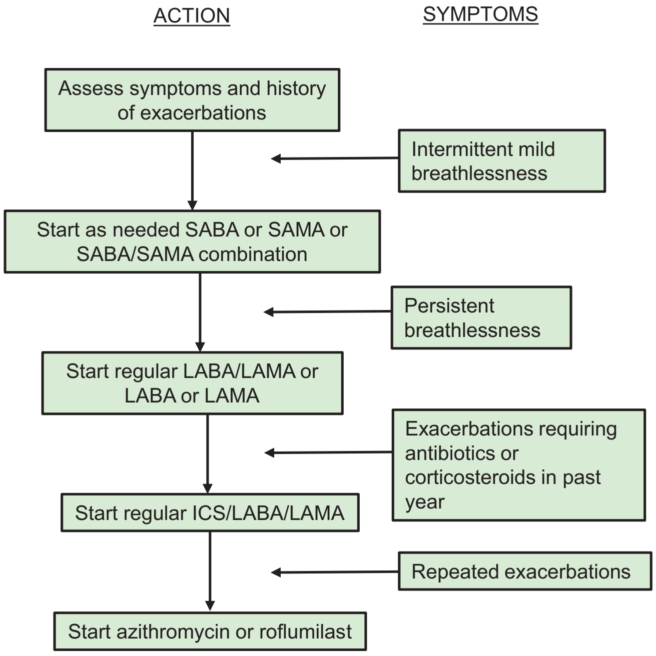
Screening for lung cancer with low-dose CT of the chest is recommended for individuals aged 50 to 80 years with a 20-pack-year smoking history who currently smoke or have quit within the last 15 years. Many individuals with COPD meet these criteria, and these individuals should undergo shared decision-making with their clinician. The discussions should include potential benefits and harms of screening.

■ Drug Therapy

Over the past several decades, the evidence base for use of drug therapy in COPD has expanded and provides an objective and generally optimistic picture that such treatment is effective. Bronchodilators and anti-inflammatory agents are used to reverse bronchoconstriction, improve lung function, improve quality of life, increase exercise capacity, and prevent exacerbations. Recent evidence however suggests that a combination of inhaled steroids and long-acting bronchodilators may improve survival as well as reduce exacerbations.[33,34] There is a poor correlation between the effect of bronchodilating drugs on lung function and symptom relief, so monitoring of treatment requires attention to patient-reported outcomes as well as lung function. Small amounts of bronchodilation can cause considerable improvement in functional capacity through decrease in dynamic exercise hyperinflation, and reduction in days of exacerbation can lead to considerable improvement in patients' quality of life.[51]

Bronchodilators

The usual approach to drug treatment for COPD is to sequentially add agents using the minimum number of agents and the most convenient dosing schedule, starting with the agents having the greatest benefit, best tolerance, and lowest cost. One approach to step-up therapy is provided in Fig. 40-2. Inhaled bronchodilators are the foundation of treatment for COPD. They are given on a regular basis to maintain bronchodilation and on an as needed basis for relief of symptoms.[52,53] Most breathless patients benefit from regular use of a maintenance bronchodilator. Both β-agonist and anticholinergic classes are available in short-duration (4–6 h) and long-duration (12–24 h) forms (Table 40-7). The choice of bronchodilator class and duration of effect depends upon the preference of the patient, a suitable device, and the cost of the preparation. Combination of different classes of bronchodilators is often more effective than increasing the dose of a single agent, and combination inhalers with long-acting bronchodilators can simplify treatment regimens.[54] Patients with advanced COPD often use a combination of bronchodilators, including long-acting maintenance anticholinergics and β-agonists as well as symptomatic use of shorter-acting bronchodilators. Individuals with exacerbations, particularly those with eosinophilia, may benefit from a combination inhaler of corticosteroids and long-acting bronchodilator.[55,56] Chronic use of systemic corticosteroids should be reserved for individuals with very frequent or life-threatening exacerbations in those cases where discontinuation of steroids cannot be tolerated. Response to treatment is judged by symptomatic improvement, functional status, frequency of exacerbations, and spirometry. If patients are doing well for 6 to 12 months on a stable treatment regimen, then it is reasonable to see if a trial withdrawal of one of the drug components can be tolerated.



ACTION
SYMPTOMS
Assess symptoms and history of exacerbations
Intermittent mild breathlessness
Start as needed SABA or SAMA or SABA/SAMA combination
Persistent breathlessness
Start regular LABA/LAMA or LABA or LAMA
Exacerbations requiring antibiotics or corticosteroids in past year
Start regular ICS/LABA/LAMA
Repeated exacerbations
Start azithromycin or roflumilast

Figure 40-2 Flow chart for pharmacologic management for people with COPD. Treatment is based on step-up therapy depending on patient symptoms and frequency of exacerbations. Patients should be re-evaluated every 3 to 12 months for step-up or step-down of treatment. Evaluation for exacerbations should be contemporaneous with evaluation for symptoms, and ICS added to bronchodilators; however, ICS should usually not be given without bronchodilators. Patients with eosinophilia have a better response to ICS. ICS, inhaled corticosteroids; LABA, long-acting beta-agonist; LAMA, long-acting muscarinic antagonist; SABA, short-acting beta-agonist; SAMA, short-acting muscarinic antagonist.

Inhaled corticosteroids do not alter the progression of COPD in those who continue to smoke.[57,58] Inhaled corticosteroids are most useful

TABLE 40-7 Inhaled Bronchodilators

Drug Name	Dosage/Frequency	Formulation
β-Sympathomimetics		
Olodaterol		Soft mist inhaler, 5 μg
Albuterol	2 inhalations q4–6h	Metered-dose inhaler, 90 μg/puff
	3 mL nebulized q4–6h	Nebulized solution 1.25–2.5 mg/3 mL
Levalbuterol	2 inhalations q4–6h	Metered-dose inhaler, 45 μg/puff
	3 mL nebulized TID	Nebulized solution 0.63–1.25 mg/3 mL
Salmeterol	1 inhalation BID	Dry powder inhaler, 50 μg/dose
Formoterol	1 capsule inhaled BID	Dry powder inhaler, 12 μg/capsule
	2 mL nebulized BID	Nebulized solution 20 μg/2 mL
Arformoterol	2 mL nebulized BID	Nebulized solution 15 μg/2 mL
Indacaterol	1 capsule daily	Dry powder inhaler, 75 μg/capsule
Anticholinergic Bronchodilators		
Ipratropium	2 puffs q4–6h	Metered-dose inhaler, 17 μg/puff
	2.5 mL nebulized q6–8h	Nebulized solution 0.5 mg/2.5 mL
Tiotropium	1 inhalation daily	Dry powder inhaler 18 μg/dose
	2 inhalations daily	Soft Mist inhaler 2.5 μg/inhalation
Aclidinium	1 inhalation BID	Dry powder inhaler 400 μg/dose
Revefenacin	3 mL nebulized daily	Nebulized solution 175 μg/3 mL
Glycopyrrolate	1 inhalation BID	Dry powder inhaler 15.6 μg/dose
	1 mL nebulized BID	Nebulized solution 25 μg/mL
Umeclidinium	1 inhalation daily	Dry powder inhaler 62.5 μg
Combination Bronchodilator Therapies		
Ipratropium/albuterol	1 puff q6h	Soft mist inhaler, 20 μg/100 μg/inhalation
Umeclidinium/vilanterol	1 inhalation daily	Dry powder inhaler, 62.5 μg/25 μg/inhalation
Tiotropium/olodaterol	2 inhalations daily	Soft mist inhaler 2.5 μg/2.5 μg/inhalation
Glycopyrrolate/formoterol	2 inhalations BID	Metered-dose-inhaler 18 μg/9.6 μg/inhalation
Glycopyrrolate/indacaterol	1 inhalation BID	Dry powder inhaler 15.6 μg/27.5 μg/inhalation
Aclidinium/formoterol	1 inhalation BID	Dry powder inhaler 400 μg/12 μg/inhalation

in patients who have features of asthma and in COPD patients who have frequent exacerbations. Eosinophilia is a biomarker that predicts a particularly good response to inhaled corticosteroids.[59] Inhaled corticosteroids combined with bronchodilators can reduce the frequency of exacerbations and slow the decline in quality of life. In patients with exacerbations, inhaled corticosteroids improve pulmonary function, and the results are additive to those achieved with long-acting bronchodilators. Inhaled corticosteroids, although poorly absorbed, probably do contribute to steroid side effects such as cataracts, capillary fragility, and osteoporosis in susceptible individuals. High doses of inhaled corticosteroids are associated with increased risk of pneumonia.[60,61] In most cases, the risk is low compared to the benefit of treatment, but it is prudent to prescribe the lowest effective dose.

Adverse effects of inhaled therapy can occur. Inhaled anticholinergic agents are generally very safe. They may lead to an increased frequency of supraventricular arrhythmias, acute urinary retention in those with bladder outlet obstruction, or acute narrow-angle glaucoma if sprayed in the eye. β-Agonists, both short acting and long acting, may lead to side effects such as tremor, tachycardia, or hypokalemia.

Inhaled agents are administered by metered-dose inhaler (MDI), dry powder inhaler (DPI), or soft-mist inhaler (SMI), or as a nebulized solution. The selection of route of administration is made by cost and convenience of the device because all are similarly effective if used properly. There are several forms of DPI, some more intuitive to use than others, so specific instruction and demonstration is required by most patients. Because DPIs may require a high inspiratory flow, some authorities recommend screening patients with peak inspiratory flow meters before prescribing a DPI.[62] Nebulizers are easier for patients to coordinate, but each treatment takes longer to complete, and they require additional effort to maintain cleanliness. Although nebulized medications are more expensive overall, the cost of the medication is often borne by insurance, so patients may prefer nebulizers for financial considerations.

Adherence with inhaled medication, particularly when it does not provide immediate symptom relief, is poor. Typically, about half of patients do not collect or use their medication in the dose or quantity prescribed.[63] Reasons for this include a lack of understanding of the role of the medication, failure of the medication to provide meaningful benefit, complexity of the treatment program, and cost of the treatment. Many patients do not want to confide poor adherence to their physician, so it is important for the physician to ascertain this information in a way that does not interfere with the relationship with the patient. For example, a physician could inquire, “It is often difficult for patients to remember to take all of their medications. Has this been a problem for you?” or “Are you able to afford all your medication?” or “Do you think that your medicines are working for you?” If nonadherence is a problem, the treating physician can undertake actions to improve adherence, such as simplification of the medication program, education about the benefits of treatment, linking drug use to established habits such as meals or tooth brushing, or prescribing less costly drugs.

Proper use of MDIs is difficult for many patients to learn and retain. Repeated review and training of patients in MDI use is an important component of treatment of COPD and asthma. The inhaler should be held about 4 cm from the mouth to minimize deposition of larger droplets in the mouth. The patient should exhale to FRC and take a slow inhalation to TLC over about 5 seconds. The slow inhalation diminishes impaction of particles in the mouth and larynx. At the initiation of inspiration, the patient should actuate the MDI one time. After full inspiration, the patient should hold the breath for about 10 seconds to permit settling of particles in the distal airspaces. If the patient finds that hoarseness or mouth irritation occurs with inhaler use, this can often be corrected by use of a spacer, slowing the rate of inspiration, and rinsing the mouth after each inhaler use. Waiting a period of time between inhalations or between different MDIs is sometimes recommended for optimal effect, but the benefit is small compared with the inconvenience and risk of worsening adherence. Therefore, it is usually appropriate to permit the patient to take additional inhalations as soon as he or she has rested a few seconds.

If the patient has difficulty coordinating the actuation of the MDI with inspiration, a spacer device or holding chamber can be used. This device is placed directly in the mouth and the MDI is actuated prior to inspiration. DPIs usually require less coordination than MDIs, but there are many different devices, some rather complicated to use. Very frail patients may not have adequate inspiratory flow to effectively use a DPI. Therefore, each device requires individual instruction and repeated review of technique.[64] (For a compendium of patient instructions, see www.copdfoundation.org/Learn-More/Educational-Materials-Resources/Educational-Video-Series.aspx)

Roflumilast is a highly specific inhibitor of phosphodiesterase 4, which is a mild bronchodilator with anti-inflammatory properties. It is marketed in the United States for reduction of exacerbations of COPD in individuals with chronic bronchitis, $FEV_1 < 50\%$ predicted, and increased exacerbation events.[65] Gastrointestinal side effects can be minimized by starting with a low dose and increasing as tolerated. Because roflumilast causes weight loss in overweight patients and improves glycemic control in type 2 diabetics, it is particularly useful in these individuals.[66]

Oral corticosteroids are effective for treatment of COPD exacerbations. About 10% to 20% of chronic symptomatic patients show substantial short-term improvement in pulmonary function, but it is not possible to identify these patients based on clinical characteristics alone. Because of the well-defined long-term adverse effects of systemic corticosteroids, and the ill-defined long-term benefits, most patients should not be maintained on long-term oral or systemic corticosteroids. Patients with COPD who are on chronic corticosteroids can most often taper the dose at the equivalent rate of 5 mg of prednisone per week, and exclusively reserve their use for exacerbations. Long-term low doses of oral corticosteroids are occasionally needed by patients who cannot afford or tolerate inhaled agents, and who suffer frequent exacerbations. Patients on long-term systemic steroids who are at high risk for osteoporosis should be considered for prophylactic treatment with bisphosphonates and should be instructed about the need for stress-dose steroids for acute illnesses.

Long-term macrolides, which have immunomodulatory as well as antibiotic properties, have been demonstrated to reduce the frequency of exacerbations in patients susceptible to frequent exacerbations.[67] These agents can be used in patients who still have exacerbations despite maintenance treatment with bronchodilators and inhaled steroids. It remains an unsettled question whether treatment with macrolides or roflumilast is superior for preventing severe exacerbations. In secondary analyses, the benefit of azithromycin appears to be present in former smokers, with minimal exacerbation reduction in current smokers.

Mucolytic agents to control mucus hypersecretion with the use of expectorants and physical means such as high-frequency chest wall oscillation or a flutter valve is not of proven benefit in improving lung function, although symptoms are sometimes improved. N-acetylcysteine, a mucolytic with antioxidant properties, does not alter the decline in FEV_1. However, antioxidant mucolytics, such as N-acetylcysteine or carbocysteine, may have a role in reducing exacerbations.[68,69]

Opiates can be effective in the management of severe dyspnea related to COPD. Given differential response to these therapies, as well as the associated potential for respiratory depression, short-acting and low-dose preparations should be initially used. While typically associated with severe, end-stage management in the hospice setting, short-acting opiates can be considered in patients with less severe lung impairment but symptomatic dyspnea refractory to pharmacotherapy, oxygen supplementation, and rehabilitation.[70]

■ Exercise and Rehabilitation

Regular, prudent, self-directed exercise is recommended for all individuals with COPD to prevent the muscle deconditioning that often accompanies the disorder. Individuals should be encouraged to perform at least 20 to 30 min of constant low-intensity aerobic exercise such as walking at least three times per week. Even the most severely impaired patients with COPD can usually attain an exercise regimen of 30 min of walking at 1 mph (i.e., one-half mile in 30 min). It is important to instruct patients that they should exercise to a level of dyspnea that is tolerable for the entire exercise period. Patients should understand that dyspnea, by itself, is not injurious to the heart or lungs, but patients should pace themselves to avoid severe dyspnea that disrupts activity, can lead to panic reactions, and is distressing to onlookers. Patients who demonstrate desaturation with exertion may be prescribed supplemental oxygen for exercise on an individualized basis. Many patients, particularly those with marked hyperinflation, find that they can ambulate better with the use of a rolling walker that supports the arms, improving the mechanical advantage of the accessory muscles in the neck. Initiation and maintenance of an exercise program as well as educational materials are increasingly available on telehealth platforms with internet connections.

Formal in-person rehabilitation programs offer a comprehensive approach to exercise training, patient education, nutritional counseling, group support, and psychological support that cannot be efficiently provided in the physician's office. Rehabilitation programs are established as an effective component of COPD management and should be offered to patients who have substantial limitation in daily activities. After hospitalization for COPD exacerbation, enrollment in pulmonary rehabilitation is associated with reduced mortality.[71] A detailed discussion of rehabilitation is provided in Chapter 42.

■ Nutritional Support

About 25% to 40% of patients with COPD show evidence of nutritional depletion. Reasons for this include increased resting metabolic demands, inadequate caloric intake due to dyspnea and anorexia, and possibly elaboration of cachexia-associated inflammatory cytokines such as TNF-α, IL-1, and IL-6. Patients with a BMI of less than 90% of normal have increased mortality and decreased exercise capacity. Muscle wasting and loss of bone mass may be present even in patients who have normal BMI.[72] Although clinical trials of nutritional supplementation have been disappointing, it is prudent to monitor body weight in patients with COPD and encourage caloric supplementation as needed since those patients who do gain weight show improved survival.[73] High-fat diets have the theoretical advantage of offering higher caloric content with lower CO_2 production than high-carbohydrate diets, but there is no convincing evidence that this strategy is clinically superior to a well-balanced diet. For patients with less advanced disease, a balanced diet with avoidance of overweight or underweight is a rational goal. Particularly, patients with mild to moderate disease who quit smoking tend to gain excessive weight, which might adversely affect lung function.[74]

■ Sleep Disorders in COPD

Sleep disturbances, including insomnia and daytime hypersomnolence, are common symptoms in patients with COPD, and are often overlooked because of the focus on breathlessness and exercise intolerance.[75] The causes for sleep symptoms are multifactorial and include anxiety, depression, resting hypoxemia, nocturnal bronchospasm, sleep apnea, and nocturnal oxygen desaturation (NOD). Patients with COPD often relate insomnia to a fear of suffocation or death during sleep, a situation that may respond to repeated reassurance, cognitive therapy, or small doses of hypnotics, anxiolytics, or antidepressants. Patients with resting hypoxemia treated with low-flow nasal oxygen often report improved sleep quality. Nocturnal bronchospasm, more common among those with an asthmatic component to their disease, may respond to longer-acting bronchodilators, or rearrangement of the dosing schedule to provide nocturnal coverage. In some cases, treatment for gastroesophageal reflux by elevation of the head of the bed and prescription of acid suppressant drugs can help.

Sleep apnea syndrome, probably not more common in COPD patients than the general community, has particularly severe complications in COPD. Patients with COPD and sleep apnea, the so-called overlap syndrome, are prone to develop pulmonary hypertension and daytime hypercapnia.[76] Accordingly, symptoms of sleep apnea such as snoring, intermittent nocturnal breathing, and daytime hypersomnolence should be sought in patients with COPD. If present, then formal sleep studies and treatment with continuous positive airway pressure (CPAP) are indicated. NOD is common during rapid eye movement sleep in patients with COPD. The causes are not entirely understood, but contributing factors include hypoventilation, ventilation–perfusion mismatch, respiratory muscle dysfunction, and increases in upper airway resistance. NOD is thought to be associated with poorer sleep quality and pulmonary hypertension. It is controversial whether NOD is associated with poorer survival. Randomized trials have shown inconclusive results about the benefit of treating NOD with supplemental oxygen.[77] There is, however, an increasing body of evidence that patients with hypercapnia have improved survival and fewer hospitalizations if treated with noninvasive ventilation at night.[78] Although evidence is limited, it is currently recommended that patients with chronic stable hypercapnia should use nocturnal noninvasive ventilation and should undergo sleep apnea screening.[79]

Current guidelines do not recommend that all patients with COPD have nocturnal oxygen monitoring, nor do they recommend treatment with supplemental oxygen or nocturnal ventilation if NOD is found. Many physicians, though, will prescribe these diagnostic studies and treatments for selected symptomatic patients, and most insurance companies will provide reimbursement for such treatment. Patients who have resting room air daytime hypoxemia should be prescribed nocturnal oxygen at the same flow rate as used during the day, and it is usually not necessary to monitor nocturnal oxygen saturation in such patients.

■ Management of Depression

Depression is a common comorbidity in individuals with COPD and is related to the lack of social support.[80] The recognition and treatment of depression is important as this comorbidity is associated with poorer prognosis, increased risk of exacerbations, and poor health status. Although there is little evidence to suggest that depression should be treated differently in COPD patients, pulmonary rehabilitation has been shown to reduce depression with COPD.

■ Air Travel

Patients with COPD do not need to avoid air travel but must be aware of the medical and regulatory issues that are involved.[81,82] Modern airplanes are pressurized to an equivalent altitude of approximately 5000 to 8000 ft but may, on occasion, pressurize to an equivalent altitude of 10,000 ft without providing emergency oxygen. Many patients with COPD who do not use sea-level oxygen can tolerate short flights without supplemental oxygen. As flight distance becomes longer, the flying altitude becomes higher and the cabin pressure becomes lower, so transcontinental or transoceanic flights should prompt medical advice. The general rule of thumb used by the commercial airline industry is that patients who can ambulate 50 m without stopping are safe for air travel. A more conservative approach is to estimate the Pa_{O_2} during air travel by performing a high-altitude simulation test (Chapter 31).

High-altitude simulation can be performed by administering 15% oxygen via a face mask or by using 100% nitrogen in a 40% Venturi mask.[83] If the oxygen saturation falls below 86% or 50 mm Hg, then supplemental oxygen is recommended. Resting arterial oxygen saturation by itself is not a reliable indicator of oxygen desaturation at altitude. However, one study showed that a resting sea-level SpO_2 >95% with a 6-minute walk test SpO_2 >84% was highly sensitive for establishing that patients were able to fly without supplemental oxygen.[84] If resting SpO_2 is <92% or 6-minute walk test SpO_2 is <84% then oxygen should be prescribed for air travel. Patients who use oxygen supplementation at sea level should increase their resting oxygen prescription by a flow rate of 2 L/min. Patients with COPD who engage in air travel should use a pulse oximeter to monitor their saturation during the flight and adjust oxygen supplementation accordingly, particularly with pulsed-dose oxygen where equivalent constant flow rates are inconsistent.

Airlines have inconsistent policies with respect to providing supplemental oxygen for travelers, so it is important to check with the airline service desk before booking travel. The United States Federal Aviation Administration has promulgated regulations that permit approved portable oxygen concentrators to be carried on board by passengers as personal luggage with a physician's statement of need. These may be rented from oxygen supply companies or specialized websites. For battery-driven portable oxygen concentrators, extra batteries should be carried aboard to accommodate delays in the flight or extended time in the air.

The COVID-19 pandemic has focused attention on the transmission of droplet-borne viral diseases during air travel, which can be injurious to people with COPD. Therefore, it is rational to recommend use of facemasks and good hand hygiene for air travel for all individuals who may be susceptible to viral infection.[85]

■ Long-Term Oxygen Therapy

Oxygen treatment of resting severe daytime hypoxemia prolongs survival.[86–88] Guidelines recommend prescribing long-term oxygen therapy (LTOT) for at least 15 h/day for adults with COPD who have severe chronic resting room air hypoxemia (defined as $PaO_2 \leq 55$ mm Hg or $SpO_2 \leq 88\%$). Oxygen is usually administered by nasal cannula, with the flow rate adjusted to maintain a resting saturation >90%. The usual starting flow rate is 2 L/min, although some patients with severe hypercapnia require lower flows. Some patients, particularly those with concomitant interstitial pulmonary disease or cardiovascular disorders, require higher flow rates.

The most convenient and cost-effective oxygen source at home is usually a concentrator device that uses a molecular sieve to extract oxygen from room air. For ambulation, small, compressed oxygen cylinders, portable concentrators, or liquid oxygen reservoirs that can be carried provide patients with the ability to leave their homes. Conserving devices, such as reservoirs or demand valves, permit portable ambulatory oxygen tanks to last up to 10 h. Compressed oxygen cylinders or liquid oxygen reservoirs should be provided by home oxygen companies to patients who use electrically driven oxygen concentrators for emergency use in the event of a power failure. Ideally, oxygen should be used constantly 24 h per day. At least 18 h of oxygen per day, however, has been shown to have substantial benefit over 12 h per day. If continuous oxygen supplementation is prescribed following an exacerbation of COPD, it is recommended to check arterial oxygen levels in 6 weeks, as many patients will no longer require oxygen.

Nasal drying or congestion is a common symptom for those who use continuous oxygen. This may be alleviated to some extent by alternating the nasal cannula from one nostril to the other or placing it in the mouth for periods. Copious watery nasal secretions often respond well to ipratropium nasal spray, and dry, crusted nasal mucosa is treated with hourly instillations of saline nasal spray.

Smoking or exposure to any open flame is prohibited by the danger of fire and airway burns in those who use oxygen. This is a surprisingly common cause of burns in the United States, with estimates that up to 50% of patients on oxygen continue to smoke to some extent.[89] Accordingly, it is safer to counsel patients to discontinue oxygen while smoking or cooking over an open flame if they insist on doing these activities. Patients at particular risk are those who live alone, have cognitive impairment, and do not have functioning smoke detectors.

Ambulatory oxygen, although not shown to improve survival, may be provided for patients who desaturate with exertion. Some, but not all, patients show improved exercise capacity and reduced breathlessness. Patients with exercise desaturation or moderate levels of hypoxemia do not, however, benefit in terms of increased survival or decreased hospitalizations.[90] There is good evidence that oxygen supplementation during exercise training may benefit COPD patients who do not have exercise desaturation by reduction in minute ventilation and decreased dynamic hyperinflation.[91] However, in sham-controlled clinical trials where oxygen treatment does not improve exercise intensity, there is no added training benefit.[92,93] Therefore, the recommendation for oxygen during exercise training should be individualized based on patient preference and shared decision-making with the provider.

COMPLICATIONS

A variety of respiratory and cardiac complications may be seen in COPD and are discussed below.

COPD Exacerbations

Exacerbations are characterized by worsening cough, dyspnea, and sputum production beyond normal day-to-day variation. These exacerbations are associated with acute deterioration of lung function during the exacerbation and may also accelerate lung function decline. Acute exacerbations of COPD are a major cause of hospitalization, healthcare costs, morbidity, and mortality in COPD. Exacerbations have been associated with respiratory viral infections including rhinovirus, respiratory syncytial virus, influenza, adenovirus, and metapneumovirus. Bacterial infections or superinfections are also associated with COPD exacerbations. The most frequent pathogens are *Haemophilus influenzae, Moraxella catarrhalis,* and *Streptococcus pneumoniae*. In patients who have been previously treated frequently with antibiotics, gram-negative bacteria also may be present. Severe air pollution, especially particulates, sulfur dioxide, ozone, and nitrogen dioxide have been associated with elevated risk for hospitalization due to COPD. On average, patients with COPD have two to three exacerbations per year, but there is wide variation, and the frequency of exacerbations is only roughly correlated with severity of airflow obstruction. The best predictor of future exacerbations is a past history of frequent exacerbations, and these are more common in patients with chronic cough and sputum production.[94] Only half of COPD exacerbations come to the attention of treating physicians, and many of these eventually resolve without specific treatment. The management of these exacerbations depends upon the severity. Indications for hospital evaluation or hospitalization are listed in Table 40-8. Arterial blood gas studies and chest radiographs are useful for evaluating etiology and severity of acutely ill patients. Spirometry during the acute exacerbation is usually not helpful in predicting the severity or duration of the exacerbation.

TABLE 40-8 Indications for Hospitalization in COPD

Indications for Hospital Assessment or Admission for COPD Exacerbation
Sudden onset of new or severe symptoms (e.g., dyspnea)
Inability to sleep or eat because of dyspnea
Severe or very severe underlying COPD
Onset of new physical findings (e.g., edema, cyanosis, change in mental status)
Failure to respond to initial medical treatment
Associated comorbidities (e.g., cardiac, renal, hepatic failure, diabetes)
Diagnostic uncertainty (e.g., suspected pneumonia or pulmonary embolism)
Frailty or dementia
Inadequate home or social support
History of poor adherence with treatment
Indications for ICU Admission for COPD Exacerbation
Severe dyspnea unresponsive to initial treatment
Change in mental status (e.g., confusion, lethargy, coma)
Persistent or worsening hypoxemia, hypercapnia, or respiratory acidosis
Need for sedation or narcotic pain control
Need for mechanical ventilation
Need for hemodynamic monitoring

Data from The 2021 Global Strategy for the Diagnosis, Management and Prevention of COPD, Global Initiative for Chronic Obstructive Lung Disease (GOLD).

For patients treated at home, increasing the frequency and intensity of inhaled short-acting bronchodilators for several days is effective in mild exacerbations. A hand-held inhaler and spacer are usually effective, but a nebulizer may be needed for those who cannot coordinate well or who have severe dyspnea. Increasing dyspnea accompanied by a change in the quantity or color of phlegm is usually an indication of bacterial infection and should prompt initiation of antibiotics. When readily available, C-reactive protein (CRP) levels are helpful in guiding antibiotic prescription.[95] The choice of antibiotic is determined by severity of the underlying disease, resistance patterns of likely pathogens, and likelihood of treatment failure (Table 40-9). For those not responding to treatment, the antibiotic should be tailored based on sputum cultures.

TABLE 40-9 Antimicrobial Treatment of COPD Exacerbations

First Line	
	Amoxicillin 500–875 mg PO TID
	Doxycycline 100 mg PO BID
	Azithromycin 500 mg, then 250 mg PO QD × 4 d
Alternatives	
	Amoxicillin/clavulanate 875 mg PO BID
	Clarithromycin 500 mg PO BID
	Second-generation cephalosporins
Previous antibiotics or known gram-negative pathogens	
	Levofloxacin 500–750 mg PO QD × 7 d
	Ciprofloxacin 500 mg PO QD × 7 d

A course of corticosteroids, equivalent to 30 to 60 mg of prednisone for 5 to 10 days, will shorten the duration of symptoms for patients with exacerbations managed as outpatients.[96–98] For patients admitted to the hospital, intensification of inhaled bronchodilator treatment, systemic corticosteroids, and antibiotics are administered.[99] Controlled oxygen supplementation should be provided at the lowest level needed to reverse hypoxemia and minimize the induction of hypercapnia. The selection of the oral or intravenous route for antibiotics and corticosteroids is determined by the severity of the illness and the ability of the patient to tolerate oral medication. Evaluation for the cause of the exacerbation does not have to be extensive if it responds to initial treatment and conforms to the patient's usual exacerbation pattern. Sputum culture for resistant bacterial strains, a chest radiograph for exclusion of pneumonia and pneumothorax, and an electrocardiogram for exclusion of myocardial ischemia and arrhythmia are useful tests in all hospitalized patients. Echocardiography for assessment of ventricular function, and D-dimer, Doppler venous flow studies, radionuclide, or CT lung imaging for evaluation of pulmonary thromboembolism need to be performed in selected cases. Usually, a 5- to 14-day course of steroids is sufficient for hospitalized patients.

Treatment in an intensive care setting should be undertaken for patients with severe exacerbations or those who require more constant attention (Table 40-8). For patients with respiratory failure, noninvasive mask ventilation has proved to be an effective strategy to avert endotracheal intubation, shorten duration of illness, and improve outcomes.[100] Attention needs to be paid to selecting and fitting a comfortable well-sealed mask, and providing a ventilator that minimizes the patient's work of breathing and triggering effort. When noninvasive mask ventilation is not successful in sustaining ventilation, or the patient is too ill to use the mask, endotracheal intubation and mechanical ventilation are needed to treat respiratory failure. The mechanical ventilator should be set to provide minute ventilation that does not overventilate the patient and cause alkalemia, which may ultimately impede liberation from the ventilator. The inspiratory flow rates and inspiratory to expiratory time ratios should be adjusted to provide a prolonged duration of expiration to minimize dynamic hyperinflation (auto-PEEP), which can lead to dyspnea, discoordination, and barotrauma. Weaning and liberation from mechanical ventilation can be hindered by anxiety, oversedation, mucus secretions, intravascular volume overload, myocardial ischemia, or respiratory muscle deconditioning. A hospitalization for COPD exacerbation should be considered a sentinel health event. Patients hospitalized for COPD exacerbation have a 25% 1-year mortality, with patients requiring mechanical ventilation having even poorer outcomes—with about a 40% 1-year mortality for those who survive the hospitalization.[101,102] Given the clinical impact of a hospitalized exacerbation, all COPD patients should have their maintenance COPD regimen reassessed at time of discharge for appropriate modifications and have close outpatient follow-up after discharge.

■ Pneumothorax

Smoking-related emphysema is thought to be the most common cause for secondary spontaneous pneumothorax.[103] A pneumothorax can either cause an acute symptomatic exacerbation of COPD from rupture of a bleb or may occur during the course of an exacerbation as a consequence of hyperinflation or mechanical ventilation. Because this is a life-threatening but quickly treatable cause for worsening respiratory failure in COPD, it should always be considered in the differential diagnosis for worsening dyspnea in COPD. The physical examination can be misleading because diminished breath sounds are a component of COPD. Imaging studies are usually diagnostic, but at times it can be difficult to distinguish a pneumothorax from an overdistended bulla. If the patient's clinical situation can tolerate it, imaging with inspiratory and expiratory views or chest CT can be helpful. In the intensive care unit, upright and cross-table lateral views sometimes show mobility of the pleural air.

Urgent treatment for the patient in extremis is performed by aspirating the pleural space at the second intercostal space anteriorly in the midclavicular line. Definitive emergency treatment is placement of a thoracostomy tube, which should be done with care to avoid laceration of a bulla and creation of a bronchopleural fistula. In patients with advanced COPD, recurrence of a pneumothorax is common and can be life-threatening, so definitive pleural sclerosis with surgical or medical thoracoscopy should be considered. If there is a persistent bronchopleural fistula, surgical intervention or endobronchial valve insertion may hasten recovery.[104]

■ Cor Pulmonale

Pulmonary hypertension and consequent right ventricular failure, *cor pulmonale*, are usually the consequence of chronic alveolar hypoxia, with secondary contributions from destruction of the alveolar capillary bed, lung hyperinflation, and increased blood viscosity.[105] Diagnosis of pulmonary hypertension and right ventricular failure can be difficult, as physical findings of venous engorgement and right ventricular hypertrophy and dilation are late signs. Peripheral edema is poorly correlated with resting right atrial pressure and may reflect fluid retention from activation of the renin–angiotensin–aldosterone system. Functional imaging studies including echocardiography or cardiac MRI are more probative for evaluation of right ventricular function. Doppler echocardiographic measures of pulmonary artery systolic pressure correlate poorly with severity of pulmonary hypertension by right heart catheterization.[106] In situations where cor pulmonale is not associated with chronic hypoxemia, investigations for pulmonary thromboembolism and sleep apnea overlap may be helpful. Once cor pulmonale is present, survival is diminished. If the pulmonary artery pressure exceeds 25 mm Hg, the average 5-year survival is diminished by 50%.[107,108]

The primary treatment of cor pulmonale consists of continuous oxygen to overcome hypoxemia and diuretic to optimize volume status. Calcium channel blockers and other vasodilators can dilate the pulmonary circulation, but they worsen hypoxemia and their benefit is not established. Traditionally polycythemia was thought to be common and an indication of poor prognosis in chronically hypoxemic patients with COPD, but recent cohort studies indicate that polycythemia is infrequent and has an uncertain effect on outcomes.[109]

■ Supraventricular Arrhythmias

Supraventricular tachyarrhythmias are common in patients with COPD as a consequence of right atrial enlargement, increased endogenous adrenergic tone, hypoxemia, and drug treatment—specifically bronchodilators. Treatment is similar to that in nonpulmonary patients; however, the presence of COPD should not prevent evaluation for treatable causes of arrhythmias such as pulmonary embolism, hyperthyroidism, or valvular heart disease, which may be difficult to diagnose in COPD patients.

Hypercapnia

Chronic hypercapnia secondary to alveolar hypoventilation can be considered an adaptive response to obstructive lung disease by decreasing the work of breathing, preventing respiratory muscle fatigue, and allowing a diminished sensation of dyspnea. The adverse effect of chronic hypercapnia is the development of alveolar hypoxia and consequent pulmonary hypertension. Accordingly, the approach to chronic hypercapnia is the use of supplemental oxygen in controlled concentrations. In patients who are very sensitive to oxygen, it is preferable to provide oxygen in controlled concentrations with Venturi masks rather than nasal cannula.

Nocturnal ventilation has been effective in reducing daytime hypercapnia in patients with neuromuscular disease and kyphoscoliosis. Nocturnal noninvasive ventilation may be used to normalize nocturnal hypercapnia in patients with stable chronic hypercapnia. Investigation for concomitant sleep apnea syndrome is recommended.[79,110]

ADVANCED TREATMENTS

For patients who have far-advanced disease evidenced by either severe breathlessness or short life expectancy, more aggressive treatments should be considered. Undertaking these treatments requires thoughtful consideration by patients and their families, and frank discussion of the risks and benefits by the medical caregivers.

Lung Volume Reduction Surgery

Lung volume reduction surgery (LVRS) is a surgical procedure that involves stapled resection of 20% to 30% of the lung bilaterally, usually from the apices. The procedure is equally safe and effective, done by median sternotomy or video-assisted thoracoscopy (VATS). The theory behind this procedure is that the remaining lung expands to fill the thorax, thereby increasing its elastic recoil pressure, which improves expiratory airflow. The reduction of lung volume permits the diaphragm to attain a more normal, domed configuration, which improves its mechanical efficiency. Moreover, the preferential removal of unventilated bullae reduces residual volume, permitting an increase in the vital capacity. While some patients show substantial physiologic and symptomatic improvement following LVRS, many do not.[111] Generally, LVRS should not be done on patients with an FEV_1 less than 20% predicted and either diffusing capacity less than 20% predicted or diffuse homogeneous emphysema on HRCT, because these patients have high surgical mortality.[112] The group of patients who fare best with LVRS are those who have emphysema predominantly in the upper lung zones and low exercise capacity despite pulmonary rehabilitation. These patients have improved survival after LVRS and show improved functional status and quality of life. Conversely, patients without upper lobe predominance (i.e., lower lobe emphysema or homogeneous emphysema), and who have adequate exercise capacity after rehabilitation, have worse outcomes after LVRS.

Surgical resection of a single large bulla is rarely indicated for treatment of COPD. Isolated giant bullae are usually the result of an expanding congenital cyst. The generally accepted indication for resection of a single large bulla is that it occupies more than one-third of the hemithorax and causes compression of normal lung. Some believe that a preserved D_{CO} is an indicator of those most likely to improve following a bullectomy.

Nonsurgical approaches to lung volume reduction using a variety of techniques to induce atelectasis of a target lobe have generally supplanted surgical lung volume reduction. Placement of endobronchial valves in regions of lung with severe emphysema without collateral ventilation can lead to clinically meaningful improvement in symptoms.[113,114] Because pneumothorax is common after these procedures, patients are often observed in hospital for several days after the procedure. Patients who achieve complete atelectasis of the target lobe have the best symptomatic and survival outcomes.[115]

Lung Transplantation

In younger patients with advanced disease, lung transplantation should be a treatment consideration. Criteria for lung transplantation referral in patients with COPD are an FEV_1 below 25% predicted, BODE index greater than 5, hypercapnia, resting hypoxemia, secondary pulmonary hypertension, and accelerated decline in FEV_1 in patients under the age of 65 years.[116] For additional information see Chapter 106.

Chronic Ventilator Support

Some patients remain on long-term ventilator support following an episode of acute respiratory failure. Most often these patients are treated in a long-term ventilator unit, but some can be managed at home with adequate support. In some cases, the goal of long-term ventilator support is to provide rehabilitation via respiratory care, nutrition, and exercise to eventually be liberated from the ventilator entirely or for substantial portions of the day. In other cases, the goal of care is to provide comfort and support for terminal care without attempts at rehabilitation. Whatever the goal, a coordinated team of physicians, respiratory therapists, physical therapists, nutritionists, social workers, psychologists, and nurses are needed to undertake the care of these patients.

The treatment of long-term ventilator patients differs from the treatment of acute respiratory failure in the intensive care unit. Ventilators are less sophisticated in terms of modes of ventilation and monitoring, but more portable. Ventilation is often performed with an uncuffed tracheostomy with an air leak to avoid complications at the cuff site. Sufficiency of ventilation is judged by noninvasive measures of oxygenation and patient comfort. Narcotics in small doses are administered for relief of dyspnea. Diagnostic studies and invasive testing are performed less frequently than in critical care units. Although the care in long-term ventilator units is complex and expensive, the quality of life experienced by patients in chronic ventilator units is similar to that of patients confined to a bed-and-chair existence by other chronic maladies. The survival of patients with COPD on long-term mechanical ventilation is less than 3 years on average and is less than those on such treatment for neuromuscular diseases, in part, because of their older age and comorbidities.[117]

CONCLUSIONS

COPD develops insidiously. However, the disease can be easily detected with simple spirometric testing before symptoms occur, and cessation of smoking can slow or even halt the disease progression and prolong survival. Once the disease is symptomatic, a coordinated, comprehensive, and individualized approach to treatment, both pharmacologic and nonpharmacologic, can increase functional status, prevent complications, and improve the quality of life. Exacerbations of COPD can range from those that are nuisances to those that are life-threatening, but treatment can shorten the duration of illness and improve outcomes. In advanced disease, treatments including surgical and bronchoscopic approaches are directed toward relief of symptoms. Thus, although there is certainly need for improvement in our treatment of symptomatic COPD, current treatments are effective, and a nihilistic attitude is not warranted.

DISCLOSURES

Disclosure of financial conflicts: During the preceding 5 years, Dr. Wise has received fees for consultation or support of research from the following companies: AbbVie, AstraZeneca, Boehringer-Ingelheim, Bristol Myers Squibb, Chiesi, ChimiRix, Circassia, Contrafect, FSD Pharma, Galderma, Genentech, GlaxoSmithKline, Kamada, Kinevant, Kiniksa, Merck, Mylan, Novartis, Pfizer, Polarean, Pulmonx, Puretech, Sanofi, Roche, Theravance, Verona.

During the preceding 5 years, Dr. Drummond has received fees for consultation or support of research from the following companies: AstraZeneca, Boehringer-Ingelheim, Enterprise Therapeutics, GlaxoSmithKline, Lupin Pharmaceuticals, Midmark, NovaVax, Parion, Polarean, and Teva, Theravance Biopharma/Mylan.

CHAPTER 41

Cigarette Smoking, Smoking Cessation, and Electronic Cigarettes

Stephen R. Baldassarri
Stephen I. Rennard

INTRODUCTION

Native Americans discovered the use of the tobacco plant, *Nicotiana tabacum*, during antiquity. By the time Columbus arrived in America, tobacco use was widespread throughout the Western Hemisphere and was well integrated into Native American cultures. Production of tobacco and its trade represented a major economic activity in the pre-Columbian Americas. Early European explorers learned of the tobacco plant from Native Americans, and by the mid-17th century tobacco was widely used in Europe.

The most important, but not the only, active psychopharmaceutical drug contained in the leaves of the tobacco plant is nicotine.[1,2] Nicotine is a major metabolic product of the tobacco plant, and it is likely that it evolved as a protection against insect predators, as nicotine is a potent insect neurotoxin.[3] Interestingly, nicotine has been exploited in this regard as a commercial insecticide. Nicotine, however, is the major addicting substance in tobacco, although the addiction to tobacco is more complex than addiction to nicotine alone. Other psychoactive compounds also are present in tobacco smoke, including monoamine oxidase inhibitors.[4] These may either have direct effects, interact with other psychoactive drugs, or both.[1,2] In addition, conditioned behavior and social interactions are important drivers of smoking.[5–8]

Nicotine is a potent euphoriant. On a molar basis, nicotine is more active than such euphoria-inducing drugs as cocaine, amphetamine, or morphine.[9] Nicotine elicits complex effects on the central nervous system (CNS), which are discussed in more detail below. Many of these effects, however, are perceived as desirable, accounting for the popularity of smoking. For example, nicotine ameliorates anxiety, reduces perception of pain,[10] mitigates symptoms of depression,[11] and induces a sense of well-being[9] while causing a state of arousal.[12] In contrast to many euphoriants that impair cognition, nicotine can improve task performance and attention time by measurable degrees in non-habituated individuals and may have beneficial effects on cognition.[12]

Despite its perceived benefits, smoking of tobacco has long been controversial. King James of England wrote in 1604 "[Smoking is] a custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs, and in the black stinking fume thereof, nearest resembling the horrible Stygian smoke of the pit that is bottomless."[13] The Surgeon General's Report of 1964 outlined the convincing evidence for the health consequences of smoking.[14] Since that time, there has been a gradual increase in efforts to control tobacco use and the associated health consequences. Changes in social attitude, public health efforts, and both pharmacologic and nonpharmacologic approaches have been developed that have meaningful benefits. The current chapter will focus on treatment designed to help a smoker achieve abstinence. An overview of the increasingly important topic of electronic cigarettes will conclude the chapter.

NICOTINE ADDICTION

Nicotine exerts its biologic effects on "nicotinic" receptors, a subset of cholinergic receptors, whose endogenous ligand is acetylcholine.[15,16] Nicotinic receptors are homo- or heteropentamers that bind two ligand molecules and form an ion channel.[17] In humans, 17 genes code for distinct component chains, resulting in a very large number of potential pentamers, although only a relatively few are believed to have a biologic role. In the brain, nine alpha and three beta receptors are expressed. However, the major receptors are composed of complexes α4β2, α3β4, and α7. The α4β2 complex incorporates other subunits, particularly α5, α6, or β3, and these may modulate the effects of ligands, including nicotine.[17] The α4β2 receptor is believed to be particularly important in the addicting effects of nicotine. Deleting the β2 receptor in mice eliminates behavioral responses to nicotine, while mutations in the gene can result in markedly increased sensitivity to nicotine.[18] The α7 receptor, for example, is believed to mediate some of the cognitive effects of nicotine, including sensory gating and learning.[18,19] In contrast the muscarinic receptors, the other major class of cholinergic receptors, are single-chain G protein–coupled receptors. Nicotine has no effect on these receptors.

Nicotinic receptors are ion channels. Upon binding of nicotine, permeability of the channel is increased.[15–18] For example, binding of nicotine to the α4β2 allows influx of calcium. This, in turn, modulates release of neurotransmitters. It is likely that the behavioral responses to nicotine result from the actions of many neurotransmitters, but dopamine is believed to be a major mediator of nicotine effects. In this context, dopamine is a key mediator of pleasure and reward and is required for the reinforcing effects that lead to drug self-administration in animal models.[20] As such, dopaminergic signaling is believed to be key in the pathogenesis of many addictions and compulsive behaviors. Nicotine also modulates the release of other neurotransmitters, including glutamate and gamma-amino butyric acid (GABA). Interestingly, chronic administration of nicotine desensitizes neurons that release GABA, which inhibits dopamine release. In contrast, there is no desensitization of glutamate release, which augments dopamine release. Chronic nicotine exposure, therefore, can lead to further augmentation of dopamine release.[21,22] Moreover, the CNS alterations that occur following nicotine administration can be very long lasting; for example, alterations in nicotine receptor levels in rats exposed in utero persist until adult life.[23] The adolescent brain may be particularly sensitive to long-term alterations induced by nicotine.[24] This may account for the sensitivity of adolescents to addiction. Persistent changes in the brain may also account for the observation that, even after achieving abstinence, a smoker is at risk for relapse and if relapse occurs, the smoker reverts to the previous "steady-state" habit much more rapidly than that habit developed initially.

Nicotine is contained in the leaves of the tobacco plant. Nicotine is a weak base and as a result will be charged in acidic environments. Many forms of tobacco, such as cigars and chewing tobacco, are alkalinized, which results in uncharged nicotine that can be more readily absorbed through the buccal mucosa. Thus, cigar smokers do not have to inhale to achieve desired blood nicotine levels. The process of smoking a cigarette is more complex.[25] Air sucked through the burning end of a cigarette becomes heated. As the hot air passes down the bole of a cigarette, it causes the nicotine in the tobacco to vaporize. As the mixture cools, the nicotine condenses on smoke particles resulting in a nicotine aerosol. Conventional cigarettes have been designed so that the resulting particle size is ideal to reach the alveolar structures of the lung. Uncharged nicotine is lipid soluble and is rapidly absorbed from the alveolar gas into the pulmonary capillary blood and then into the arterial circulation. Inhaled nicotine, therefore, reaches the brain in about half a circulation time or about 15 to 20 s. In its neutral form, nicotine readily crosses the blood–brain barrier and exerts its psychoactive effects. A cigarette, therefore, is a very effective means of delivering nicotine to the brain. It also allows a smoker to control the dose of delivered drug with considerable precision.

After absorption, nicotine distributes into various body pools. This results in a marked difference between arterial and venous nicotine levels and a rapid drop in nicotine levels upon completion of a cigarette.[26] Nicotine is then catabolized by several enzymes. The most important of these is CYP2A6, which oxidizes nicotine to cotinine and cotinine to hydroxycotinine.[27] Nicotine can also be oxidized by alternative CYP450 enzymes and may be inactivated and excreted by glucuronidation. Genetic variants in nicotine metabolizing enzymes can influence smoking behavior. In normal metabolizers, nicotine is cleared with a half-life of about 2 h. As a result, nicotine levels increase throughout the day for individuals who smoke steadily. The increase in nicotine levels can result in levels believed to fully saturate all nicotinic receptors.[1,2] In this setting, it is likely that smoking behavior is more dependent on conditioned responses than on psychopharmacologic effects of nicotine. Conversely, nicotine levels fall at night. The drop in nicotine levels is thought to initiate the early stages of withdrawal. Importantly, the lower levels allow for nicotinic receptors to be in the unbound state. As a result, the first cigarette in the morning can have a large psychodynamic effect. This is well recognized by smokers who will often report that the "most enjoyable" cigarette is the first one smoked in the morning. In addition, the drop in nicotine levels is thought to initiate the early stages of withdrawal. How long it takes a smoker to smoke the first cigarette of the day, therefore, serves as a gauge of addiction, with short times indicating stronger addiction. Smoking within 30 minutes of awakening is a key question in the Fagerstrom test for nicotine dependence.[28]

Several lines of evidence support genetic influences on smoking behavior.[29–32] Twin studies suggest that genetics accounts for about 50% of the variance in smoking. Interestingly, there appears to be a genetic basis for withdrawal symptoms.[33] A number of genes have been suggested to play a role in both candidate gene and in genome-wide association studies. Although many of the candidate genes have been difficult to reproduce, an extremely strong signal has been consistently observed in a region of chromosome 15 that includes the genes for three nicotinic receptors.[34] Among COPD patients, this region is also associated with intensity of smoking assessed by cigarettes smoked per day, suggesting it may be related to intensity of addiction.[35] As might be expected of a gene related to smoking behavior, this region has also been strongly linked to the risk for several smoking-related diseases.[36–39] Candidate genes include not only genes in the dopamine pathway, but also other neurotransmitter pathways as well as cell adhesion molecules that are thought to contribute to long-term memory and neural adaptation.

Genetic variation in nicotine metabolizing enzymes has received particular attention.[31] Many but not all studies have demonstrated that individuals with variants in CYP2A6 who metabolize nicotine slowly smoke fewer cigarettes and maintain lower cotinine and carbon monoxide levels consistent with their requiring less total intake.[35,40,41] Consistent with a reduced level of smoking, some studies have shown reduced risk for cancer in slow metabolizers.[42,43] Similarly, better lung function has been reported among individuals with haplotypes associated with slow metabolism compared to those with genes associated with rapid metabolism who smoke the same number of cigarettes.[44]

It is plausible that the slower decline in blood nicotine levels associated with slow nicotine metabolism makes these individuals less likely to experience withdrawal. In addition, the persistence of nicotine may decrease the "reward" of smoking. Both of these effects may contribute to increased likelihood that a slow metabolizer can achieve abstinence from smoking,[40] and better quit rates have been observed among slow metabolizers in clinical trials.[31,45] On the other hand, slow metabolizers who are experimenting with smoking may have higher and more sustained nicotine levels. Consistent with this, a prospective study of adolescents observed a threefold risk of becoming a regular smoker among slow metabolizers.[46]

Smoking cigarettes is more complex than nicotine addiction. Conditioned behaviors also play a key role.[1,2] In this context, a smoker typically inhales 10 puffs per cigarette. This would be 300 puffs for a 1.5-pack-per-day smoker or more than 100,000 puffs annually. In addition, smoking frequently occurs in recurrent settings: after eating, when irritated, when bored, when sad, in specific social settings, etc. As such, smoking becomes associated with these settings that serve as operant cues to induce smoking behavior. Nicotine, moreover, has been demonstrated to increase both the intensity of operant conditioning as well as its persistence.[6,47] The development of addiction to tobacco, therefore, involves not only development of addiction to nicotine, but also acquisition of conditioned behaviors, which nicotine facilitates. Because these cue-mediated behaviors can be very persistent, they are major causes of relapse.

Tobacco addiction most commonly begins in late childhood or adolescence,[48–51] although smoking can begin in young adulthood.[52,53] Historically, in the United States, the peak incidence for developing a regular tobacco habit is in adolescence. Individuals who do not acquire a habit prior to age 20 are unlikely to do so as adults.[48] The demographics of smoking initiation have been well known to the tobacco industry. Marketing campaigns designed to promote the image of specific brands of cigarettes were carefully designed and were exceedingly effective in leading to historic logo recognition among children as young as kindergartners[51,54] and contributed to brand selection among American adolescents. The susceptibility of children to these campaigns was a major driver in leading to bans on tobacco advertising in media likely to be seen by children. Importantly, since most exploratory smoking occurs in peer-related social settings, the social context of smoking is a crucial variable in determining smoking initiation.[51,55,56]

Most children who begin to smoke do so on an occasional basis. Within a few years, however, a regular habit may develop. Most often this habit is characterized by smoking only a few cigarettes daily. As noted above, slow metabolizers may be particularly susceptible to addiction due to higher nicotine levels and longer persistence.[46] The number of cigarettes smoked, however, generally increases for the first 8 to 10 years. Important variations on this pattern exist, suggesting biologic differences among smokers. Some smokers achieve a "mature addiction" very rapidly. In contrast, as many as 15% of smokers, termed "chippers," may continue to smoke episodically and may not be fully addicted.[57,58]

Smoking is more common among those with psychiatric disorders.[59–61] This includes individuals with depression, anxiety disorders, and cognitive disorders such as schizophrenia, as well as other drug dependencies. The basis for this relationship is unclear. Nicotine has modest antidepressant and antianxiety effects, and the suggestion has been made that some individuals with mood disorders may smoke to "auto-medicate." Alternatively, it has been suggested that smoking and psychiatric disorders may share common genetic risk factors. Another possibility is that smoking early in life may lead to alterations in the CNS that may lead, in turn, to psychiatric disorders. In support of this, smoking more commonly precedes first psychotic episodes.[61] Whatever the mechanisms, the concurrent presence of psychiatric disorders can complicate efforts to achieve smoking abstinence.

Once a smoker achieves a "mature" addiction, cigarette consumption typically remains very constant. Interestingly, the smoker appears to adjust both nicotine intake and number of cigarettes smoked independently. If supplemental nicotine is administered, smokers will often reduce their cigarette-derived nicotine consumption.[62] Alternatively, if smoking is restricted, for example, by decreasing the number of cigarettes available, smokers will alter their smoking strategy, for example, by smoking each cigarette more deeply, to maintain a relatively constant nicotine intake.[63] Similarly, acidification of the urine increases while alkalinization slows nicotine clearance, and there are corresponding increases and decreases in nicotine intake that are achieved with no change in the number of cigarettes smoked.[64] Rather, smokers alter the way in which individual cigarettes are smoked, that is, the depth and duration of inhalation and the number of puffs, thus modifying the nicotine absorbed. Consistent with self-regulation of nicotine administration, low–nicotine-content cigarettes do not result in lower nicotine consumption.[65] This illustrates the complexity of smoking where both nicotine addiction and conditioned behaviors contribute.

While the pathogenetic mechanisms underlying withdrawal symptoms are incompletely understood, it is generally believed that some withdrawal symptoms are related to decreases in nicotine blood levels below certain thresholds. Variations in nicotine metabolism would be expected to affect the timing of symptom onset. Some smokers, for example, may experience nicotine withdrawal at night when sleep interferes with nicotine intake.[66] The use of nicotine replacement to help ameliorate withdrawal symptoms by maintaining nicotine blood levels is also an important concept underlying nicotine replacement as an aid to smoking cessation. In addition, susceptibility to specific symptoms may be genetically determined.[67,68]

SMOKING AS A PUBLIC HEALTH PROBLEM

Cigarette smoking is a major public health problem and is, perhaps, the most important cause of preventable disease. The number of deaths attributed to cigarette smoking in the United States has been estimated to be well in excess of 400,000 annually and has been for many years.[69,70] This exceeds deaths attributed to other specific causes with the recent exception of COVID-19.[71] The health burden attributable to smoking parallels smoking prevalence. As a result, smoking-induced disease is becoming more common in the developing world where smoking prevalence has been increasing, particularly in specific subpopulations such as young and middle-aged males.[72] In the United States, after comprehensive tobacco control programs were reduced, smoking prevalence and the burden of tobacco-related disease began to decrease.[73–75] Smoking can cause disease through a variety of mechanisms, which are reviewed in other chapters. However, some pathophysiologic effects persist after cessation. Smoking-related disease, therefore, will continue to be a major health problem for many decades.

Since Dr. Luther Terry released the first Surgeon General's report on smoking and health in 1964,[14] the prevalence of adult smokers in the United States has dropped from 40% to under 14%, although the rate has been relatively stable for the last decade.[75] Antismoking awareness has increased worldwide to the extent that smoking bans have become commonplace in public buildings, workplaces, and public transportation. In 1984, Surgeon General C. Everett Koop[76] proclaimed that the United States' number one health goal was to achieve a smoke-free society by the year 2000. Unfortunately, this goal was not achieved, but the public health initiatives that followed had long-lasting effects, evidenced by the continually decreasing overall incidence of smokers in the adult population in the United States.[73–75] A more realistic goal of adult smoking reduction to 12% in the United States was put into place through the Healthy People 2010 program.[77] Whether this goal will be obtained remains to be determined; however, it still highlights the importance of a smoke-free society. As of 2020, cigarette smoking reached an all-time low of 13.7% where it has remained.[76,77] However, this has been associated with a marked increase in vaping among youth (see below). The greatest reductions in smoking have been in states with the most comprehensive tobacco control programs, supporting the effectiveness of currently available interventions.

Public health approaches to control smoking-related disease begin with the social factors that are key in initiating and maintaining smoking.[51] The experience a child has with the initial attempts at smoking appear to be important, as is an individual's attitude toward smoking—that is, the "image" of the smoker, peer pressure, parental cigarette use, and availability.[51,78,79] Social attitudes can account for very low smoking prevalence in some groups. These observations support attempts to place restrictions on smoking in public places and other efforts to "de-normalize" smoking.[51]

As in ancient America, the use of tobacco products has become well integrated into modern cultures worldwide. Tobacco is a multibillion-dollar industry. In some regions, tobacco is a crucial cash crop in an agricultural economy. In addition, the manufacturing, distribution, marketing, and sale of tobacco products employ many individuals worldwide. Taxation on tobacco products has become an important means for the support of many governments. Thus, any changes in tobacco usage are likely to have economic impacts well beyond any health effects.

The use of tobacco has not only an economic role, but a cultural one as well. In some societies—for example, certain Native American tribes—tobacco usage has religious significance. In other groups, tobacco usage is associated with a strong cultural "image." Often this image may have been created through direct efforts of the tobacco industry to market their product. In this regard, advertising messages promoting the image of the cigarette smoker as rugged, independent, and masculine or as sophisticated, independent, and feminine have been developed.[80,81] While these images of cigarette smoking have their origins in advertising campaigns, the effectiveness of such marketing programs cannot be underestimated.[51,79] The portrayal of these images in media, such as film, may help promote smoking, which supports restrictions on advertisements as part of public health initiatives directed at tobacco control.[51,82,83] Whatever the reasons, cigarettes clearly have a cultural significance. The social and economic impact of tobacco usage, therefore, must be considered when attempting to deal with smoking as a public health problem.

In an effort to combat the public health ramifications of tobacco usage in the United States, the Master Settlement Agreement was signed into effect in 1998.[84] It served as a measure to recoup what states had lost through Medicaid expenditures due to smoking-related illnesses and as a measure to fine the tobacco industry for deceitful actions. Four major U.S. tobacco companies awarded 46 states $206 billion to be paid over 25 years and to be utilized as the states saw fit. Four states had previously settled separately. Unfortunately, since its inception, many states have failed to use the funding for tobacco control causes, instead using it to fill budget deficits or to support other state programs. Among many other actions, the agreement also prohibited advertisements targeted at youth and permitted access to tobacco industry documents. Based on current understanding of the complex factors that interact to cause tobacco addiction, these approaches are rational. The issues are also complex and controversial. It is likely that social and public health interventions will continue to evolve and be part of ongoing political debate.

SMOKING PREVENTION

As noted above, smoking initiation is generally a pediatric problem.[51] Precisely why some children begin smoking is not fully understood, although both social and genetic factors contribute as discussed above.[51] Currently, as many as 13.8% of American children experiment with cigarettes by the twelfth grade.[85] A number of factors are believed to contribute, including the child's social environment and the child's attitude toward smoking, which appears to be based, in large part, on the smoking behavior of parents, friends, and peer group role models.[51,78,79] Attitudes toward smoking appear to be important factors leading to smoking initiation, which may depend, at least in part, on advertising and marketing programs, hence the effectiveness of bans on advertising. The reasons for initiating smoking, however, are not entirely environmental, as several lines of investigation (see above) suggest a genetic basis for smoking as well. These concepts support the basis for interventions to reduce smoking initiation. Interventions aimed at altering the social milieu have benefit.[86] Participation in sporting activities is associated with lower rates of smoking initiation.[48,87]

A second approach to limiting smoking initiation is to restrict the sale of tobacco products to minors. Many states have legal restrictions on such sales. In many cases, however, these laws are not enforced. Active enforcement, however, can lead to a decrease in sales to minors[88] and a decrease in both experimental smoking and in regular cigarette use among younger smokers,[89] although the general effectiveness of these measures is unclear.[90] For such measures to be effective, they must be uniformly enforced in the community, and vending machines must be made inaccessible to minors.[91,92] Another approach to restrict tobacco usage by minors is taxation.[93] While there is controversy over how "elastic" purchase of tobacco is,[94] increasing price decreases use, and this effect may be particularly prominent among less addicted smokers.[93] Inasmuch as adolescents may have less disposable income, the effect may be even greater among adolescents. Some analyses support an association between higher price, particularly through taxation, and lower smoking initiation and prevalence.[95] However, assessment of the specific effectiveness is difficult methodologically.

Measures aimed at restricting tobacco sales to minors may lead to a deferral for smoking initiation, as young adults remain at risk for smoking initiation.[52,53] Thus, if measures are effective at delaying smoking initiation among children, parallel measures may also be required to affect smoking initiation among older adolescents and young adults. Currently available data suggest that smoking behavior among high school students decreased steadily since the initiation of efforts designed to reduce initiation. There does not appear to be a corresponding increase in smoking among older individuals, which supports the concept that smoking prevention is a legitimate and achievable public health goal. While it is difficult to determine the effectiveness of specific public health initiatives,[96] the evidence is clear that smoking rates can be decreased by population-based measures and that states with the most comprehensive programs have achieved the greatest gains.[51,73–75]

SMOKING CESSATION

Below we consider a general approach to smoking cessation, patient evaluation, and a variety of nonpharmacologic and pharmacologic approaches to management. We also address practical concerns in a smoking cessation program.

Background and General Approach

Smoking should be regarded as a primary addictive disorder.[97] This contrasts with the "classic" view of smoking as a "habit" or "life style choice." It has been estimated that 75% of American smokers wish to quit but only 3% are able to achieve prolonged abstinence in any year, which indicates the involuntary nature of the established addiction.[98] In addition, current concepts suggest smoking should be regarded as a chronic relapsing disorder.[99] In this context, a "cessation attempt" should be regarded as an attempt to induce a remission. The abstinent smoker, moreover, should always be viewed as at risk for relapse. The goal for therapy is to induce a remission that is as durable as possible. However, the clinician needs to be prepared to re-induce remission in the event that relapse occurs. Smokers who are "quit" should remain in active surveillance, and relapses should not be regarded as "failures." The health consequences of smoking should be regarded as secondary effects. Importantly, there are health benefits of cessation that are well established. These are the subject of the 2014 Surgeon General's Report.[100]

Current recommendations are to assess smoking and willingness to quit at every visit.[97,101] Interestingly, success in quitting may be related to acute problems that may have motivated a patient to be willing to consider quitting (see "Stages of Change and Smoking Cessation," below).[102] This acute motivation may be present even if the acute event is not directly related to smoking, and the clinician should be ready to utilize these windows of opportunity. In contrast, not inquiring about smoking can have adverse effects. Not asking is thought to send three messages: (1) that the physician does not care if the patient smokes; (2) that the physician does not have an effective intervention to offer; and/or (3) that the physician does not think that the patient will be able to quit. All of these "non-messages" have negative effects, particularly as smokers gradually make the decision to quit. A sense of empowerment and control over the behavior is believed to be key to making and succeeding in a quit attempt[103] and to subsequent risk of relapse.[104] Inadvertently eroding a patient's sense of mastery is an unanticipated adverse consequence of not asking about smoking. In addition, many patients are unaware of the potential available therapies; appropriate information can increase motivation to engage in quit attempts. Smokers unwilling to make a quit attempt should be encouraged as much as possible, provided with specific information if desired, and reminded that the issue will be brought up again in the future.

Approach to a Quit Attempt

A smoking quit attempt should be approached in a similar way to induction of remission from cancer. As with cancer, each patient should be given the best chance of achieving remission. In general, this will require two classes of intervention: nonpharmacologic approaches and pharmacotherapy, which should be used together to optimize success.

Evaluation

As with the management of any complex disease, smokers should undergo an initial organized assessment.[97,105] Motivation or reason to quit and the patient's confidence in their ability to stop smoking, that is, self-efficacy, should be assessed. For patients who indicate they are not currently interested in quitting, the goal is simple: to move them through the stages of change[106] so a quit attempt will be made. For some, this may be as simple as providing information about health risks. For others, it may be information about effective interventions. Motivational Interviewing is an effective technique used to guide patients toward change.[107] It allows patients to discover their own internal motivation through a nonjudgmental process of exploration. The provider provides empathy, rolls with resistance, respects patient autonomy, and empowers the patient to make changes on their own terms and at their own pace.

The intensity of addiction can be assessed with the Fagerstrom test for nicotine dependence (Table 41-1).[28] The most important question is time to first cigarette, and smokers who smoke within 30 minutes of awakening are usually heavily addicted to nicotine. These patients and those with Fagerstrom scores ≥7 constitute a group of individuals likely to benefit from nicotine replacement therapy (NRT) and varenicline and more efficacious as monotherapy as compared with bupropion. In contrast, patients with low Fagerstrom scores who are able to cope with smoke-free environments for an extended time period (>4 hours) without developing

TABLE 41-1 Items and Scoring for Fagerstrom Test for Nicotine Dependence

Questions	Answers	Points
1. How soon after you wake up do you smoke your first cigarette?	Within 5 min	3
	6–30 min	2
	31–60 min	1
	After 60 min	0
2. Do you find it difficult to refrain from smoking in places where it is forbidden, e.g., in church, at the library, in cinema, etc.?	Yes	1
	No	0
3. Which cigarette would you hate most to give up?	The first one in the morning	1
	All others	0
4. How many cigarettes/day do you smoke?	10 or less	0
	11–20	1
	21–30	2
	31 or more	3
5. Do you smoke more frequently during the first hours after waking than during the rest of the day?	Yes	1
	No	0
6. Do you smoke if you are so ill that you are in bed most of the day?	Yes	1
	No	0

discomforting withdrawal symptoms may not require NRT. For these individuals, the benefit of pharmacologic support is unknown.

Past experience with quit attempts should be reviewed. Many patients will have a number of prior tries. Individuals who had particular difficulty with withdrawal symptoms should be prepared for this, and medications can be gauged to attempt to mitigate their intensity. Approaches that achieved abstinence, but were followed by relapse, should be considered as they are likely to succeed again. In these cases, interventions should be guided by reducing risks of relapse.

■ Nonpharmacologic Approaches

Nonpharmacologic approaches provide the smoker with guidance and support as progress is made through a quit attempt.[97,105] It is likely that effective support improves adherence with pharmacotherapy and results in therapeutic synergy. In addition, conditioned responses, that is, cue-driven behaviors, are largely dealt with thorough behavioral strategies. This generally requires individual interviews to define individual smoking patterns. These patterns can also help identify situations that increase risk of relapse. In general, success increases with the intensity of support, but most smokers will decline referral to intensive programs and will receive only the support provided in the office setting. The remainder of this section summarizes commonly used approaches.[97,105,108]

Stages of Change and Smoking Cessation

The Stages of Change model has been very useful to guide behavioral support. Prochaska and DiClemente[106] described the smoking cessation process as involving five stages: precontemplation, contemplation, preparation, action, and maintenance. These stages are viewed as a continuum with smokers progressing sequentially through each stage. In the precontemplation stage, smokers are not interested in quitting smoking and will likely be nonresponsive to direct intervention. Smokers in the contemplation stage are considering quitting smoking and may be receptive to a physician's advice about the risks and benefits of quitting. In the preparation stage, smokers are actively preparing to quit. The action stage encompasses both initial abstinence and the 6-month post-cessation period. The maintenance period commences after the 6-month abstinence period. It is rare for a smoker to progress successfully through these stages in the initial quit attempt. The cycle will likely be repeated several times before smoking a prolonged abstinence, that is remission, is achieved. Thus, the clinician must be encouraging and willing to support repeated attempts.

The National Cancer Institute's (NCI) recommended model for smoking intervention is based, in part, on five NCI-supported trials involving more than 30,000 patients and was later expanded by the Public Health Service.[97,105] This approach, popularly referred to as "the five A's," emphasizes the role of medical professionals to ask patients about their smoking status, assess their willingness to make a quit attempt, advise smokers to stop, assist them in their stop smoking efforts, and arrange for follow-up visits to support the patient's efforts. This approach utilizes brief intervention techniques and emphasizes the role of physicians as facilitators in the quitting process.

Simple advice has been assessed in a number of studies, and meta-analysis suggests a small but significant benefit of these limited interventions.[97,105] Physician advice is effective both in the outpatient and hospital setting and may also be effective when given by letter, email, or telephone.[109–111]

Group Counseling

Group counseling programs for smoking cessation are offered by several commercial and voluntary health organizations. These programs are similar in content and typically include lectures, group interactions, exercises on self-recognition of one's habit, some form of tapering method leading to a quit day, development of coping skills, and suggestions for relapse prevention. Group counseling programs sponsored by voluntary health organizations are generally the best cost value for smokers. However, these programs are generally limited to large metropolitan areas and are offered on a sporadic basis. One-year success rates associated with group counseling programs are typically in the 15% to 35% range.[97,105] The high success rates are likely affected by selection bias, that is, participants may be more motivated to quit.

Gradual Reduction Versus Abrupt Abstinence

It is unclear whether gradual reduction in cigarettes smoked per day or abrupt abstinence is the better method for achieving prolonged smoking cessation; results may depend on individual factors.

The optimal approach probably requires customization to the patient's specific needs. Gradual reduction or tapering intuitively appears to offer smokers the least abrasive way to stop smoking and may be effective for some.[112–114] However, gradually cutting down can be stressful when smokers attempt to reduce their cigarette use below their critical blood nicotine threshold. At this stage, smokers may begin to experience tobacco withdrawal symptoms. Rather than suffer prolonged discomfort, many taperers will gradually return to their customary cigarette levels and will not succeed in quitting. One of the negative consequences of tapering is that this method can strongly reinforce the smoker's belief of their underlying need for cigarettes; that is, it can undermine self-efficacy. Combining tapering with pharmacotherapy to prevent withdrawal may be useful in this setting.[113] In this context, gradual reduction with varenicline is included in package label. Abrupt abstinence is often stressful and can lead to tobacco withdrawal symptoms. However, within a few weeks of total abstinence, complete abstainers experience less frequent cigarette cravings than taperers and are less prone to relapse. Cigarette tapering is often a component of many group programs in which gradual cigarette reduction is used as a preparatory stage leading toward a target quit day.

Educational Techniques

For years, cigarette smoking was viewed as largely a social or psychological habit. As such, the ability to quit was viewed as a measure of personal motivation and psychological willpower. Motivation to stop smoking, combined with sufficient psychological resources, was seen as a driving force behind successful cigarette abstinence. Thus, if smokers could be educated about the health risks of cigarette smoking, they could theoretically become sufficiently motivated and psychologically empowered to quit. Unfortunately, anticipated benefits of the smoking cessation value of educational awareness messages were overly optimistic and simplistic. Educational programs to aid smoking cessation have produced disappointing results with high long-term failure rates.[97,105] Nevertheless, education about smoking is still regarded as a useful activity, particularly when the information can address problems of specific interest to individual patients. In this regard, as noted above, a major predictor of success is "self-efficacy," which is the patient's sense that they are likely to succeed. Education that improves self-efficacy should be a therapeutic goal.

Other Modes of Smoking Cessation

The goal of hypnosis in smoking cessation is to enable the smoker to achieve an altered state of consciousness to enhance the ability to quit. Controlled trials of hypnosis have generally been unable to document long-term smoking cessation efficacy. While one meta-analysis suggested the possibility of a treatment effect,[115] this was not supported in another meta-analysis.[116] Aversive conditioning is based on the premise that smoking is a learned response that can be extinguished by creating an association between smoking and a negative sensation. By design, aversive conditioning techniques can produce smoker discomfort and are now rarely employed. However, there are few recent studies, and a treatment benefit cannot be excluded.[115] Acupuncture has been advocated, but controlled trials with "sham" acupuncture have not clearly demonstrated an effect. Meta-analyses have not been conclusive but suggest the possibility of an effect.[115]

Available Resources

The resources available to support smoking cessation vary among communities. Some have readily available and affordable group programs, while these may be unavailable in other places. Toll-free tobacco quit lines are currently provided by many countries, including the United States and Canada. Telephone counseling is an effective smoking intervention.[111] Thus, clinicians should encourage every smoker who wishes to quit to utilize a National Quit Line (e.g., in the United States: 1-800-Quit-Now). Additional support can be found via the internet using smokefree.gov. Using this approach, a smoker can choose to talk with a telephone specialist with either internet instant messaging or telephone support. Both methods are designed to provide smokers with a personalized quit plan that would be available in most clinical settings.

■ Pharmacologic Treatment

Three classes of agents, nicotine replacement, bupropion, and varenicline, are approved to aid smoking cessation.[117] In addition, two other agents, clonidine and nortriptyline, are supported by guidelines for "off-label" use as secondary agents. In addition, several other agents are under active investigation and have shown promise.[97,105,117] As noted above, combination of nonpharmacologic support and pharmacotherapy optimizes success in achieving abstinence. The remainder of this section summarizes currently available pharmacotherapy.

Nicotine Replacement Therapies

Five nicotine replacement therapies are approved for use to aid in smoking cessation. Lozenges, polacrilex (gum), and transdermal systems are available over the counter (OTC). Nasal spray and a nicotine inhaler are available with a prescription. Initial concerns about potential hazards of concurrent smoking while using NRT led to warnings against this practice. However, the U.S. Food and Drug Administration (FDA) removed this warning from the OTC formulations, as the benefits of smoking cessation greatly exceed any potential hazards.

NRT is usually started on the scheduled quit day. The concept is to replace nicotine that would be absorbed from cigarettes and thereby reduce the intensity of withdrawal. Smokers will, however, experience withdrawal symptoms—albeit with less intensity. In clinical trials, the five approved formulations have demonstrated about twofold increases in quit rates above placebo when used alone,[97,105] and one trial comparing gum, inhaler, and nasal spray found no difference in efficacy.[118] They differ, however, in their pharmacokinetics.[119] Transdermal systems provide the slowest delivery of nicotine but maintain steady-state levels throughout the day. The other formulations allow episodic dosing. A common practice is to combine a transdermal system with another formulation, a "patch-plus" regimen.[120,121] This allows a smoker to increase nicotine delivery at times of urges. Clinical trial data support better success with combined NRT compared to monotherapy.[97,105]

Nicotine Polacrilex Gum Nicotine polacrilex gum was the first NRT to gain FDA approval. It is now commercially available OTC in 2- and 4-mg forms. In nicotine polacrilex, nicotine is bound to a resin that contains a buffering agent to improve delivery of nicotine through the buccal mucosa. The rate of chewing can influence the rate of nicotine release. In addition, acid foods or drinks convert nicotine base to its salt, which, because of its charge, does not cross the buccal mucosa. To be absorbed into the venous circulation, the nicotine-containing saliva must be retained in the mouth as long as possible. If swallowed, the nicotine can cause local irritation of the stomach. When absorbed into the portal circulation, high first-pass metabolism in the liver limits blood nicotine levels. If chewed properly, absorption takes place gradually, and blood levels peak after about 30 minutes.[119] Ad lib use of 2-mg nicotine polacrilex is associated with blood nicotine levels less than 40% of customary smoking. The 4-mg dose is recommended for individuals who are heavier smokers or who have had discomforting tobacco withdrawal symptoms on the 2-mg dose.[97,105] A fixed dosage regimen, rather than ad lib usage, may have better success,[122] perhaps because it can produce higher blood nicotine levels. A common recommendation is that a smoker use one piece of gum every 1 to 2 h for the first 6 weeks after quitting followed by gradual reduction over 6 weeks. Many smokers continue to use gum at times of craving for an extended time, and some can use sufficient gum to sustain nicotine addiction without smoking.

Although effective in clinical trials, less successful results have been observed with nicotine gum in general practice and unsupervised settings. This may be due, in part, to requirement that the gum be chewed properly. Adverse effects from the gum include exacerbation of local effects: temporomandibular joint (TMJ) disease, trauma to dental appliances, sore jaw, oral irritation or ulcers, and excess salivation; effects from swallowed nicotine: hiccups; and effects from systemic absorption of nicotine: nausea, vomiting, abdominal pain, constipation, diarrhea, palpitations, and headache. Use of the gum is not recommended in individuals with poor dentition or who have dental appliances.[117]

Nicotine Polacrilex Lozenge A nicotine polacrilex lozenge is also available "over the counter." Chewing is not required, but acid food and/or beverages will impair absorption as with gum. Dosing, absorption, and duration of therapy with the lozenge are similar to those for the gum.[123] Because it is not chewed, the lozenge does not share the problems of exacerbating TMJ disease or damaging dental appliances. Other side effects are similar to those of the gum.

Transdermal Nicotine The primary advantage of transdermal patch delivery systems are ease of use and controlled drug delivery. Several formulations are available "over the counter." In general, they achieve nicotine blood levels roughly 40% to 50% of that achieved by customary smoking of about 30 cigarettes daily.[117] Transdermal nicotine systems have been repeatedly found to reduce tobacco withdrawal symptoms and significantly enhance smoking cessation rates.[97,105] Unlike nicotine polacrilex gum, transdermal nicotine systems and the nicotine lozenge have improved quit rates in primary care settings.[102,124] This difference is likely due to the ease of patch use in this setting. The recommended use period for patches varies according to product, but a minimum of 4 weeks of therapy is probably required to help achieve long-term abstinence. Long-term patch use is safe and likely beneficial for many smokers.[125]

Patches are most commonly worn at night, providing a level of nicotine when a smoker awakes. Often this is a time when the individual is at risk to relapse, since the low nicotine levels are associated both with withdrawal and with increased effect of the smoked cigarette. On the other hand, delivery of nicotine at night may disturb sleep, particularly through vivid dreams or insomnia. Spontaneous long-term use of the patch has not been observed, suggesting that the very slow kinetics of nicotine delivery with this system is insufficient to sustain addiction effectively.[126] In addition, perhaps due to the partial replacement of nicotine, most smokers on patches will still experience some tobacco withdrawal symptoms during the first few days of quitting. While these symptoms will likely be less severe compared to quitting cold turkey, some patients will be tempted to smoke and wear patches. Early concerns about increased cardiac risk among individuals who smoked while wearing the patch have not been substantiated. In fact, reduced smoking may decrease cardiac events.[127]

Nicotine Inhaler The nicotine inhaler is a plastic nicotine-containing cartridge that fits on a mouthpiece. Nicotine is released when air is inhaled through the device, which is similar in size to a cigarette. The nicotine is not effectively delivered to the lungs as the particle size is too large. Rather, it is deposited and absorbed through the buccal mucosa, which results in pharmacokinetics that resemble nicotine polacrilex. Blood levels depend on the frequency of inhalations but can be about one-third of conventional smoking. Usual dosing is 6 to 16 cartridges per day for 6 to 12 weeks followed by gradual reduction over 6 to 12 weeks. Because the use of the inhaler recapitulates many of the actions associated with smoking such as the preparation of the device, oral stimulation, inhalation, and others, the inhalers may be particularly effective in smokers for whom these behaviors are particularly strongly conditioned. In addition to the adverse effects described for the lozenge, the inhaler may cause irritation of the throat and mouth and may precipitate bronchospasm in individuals with reactive airways.

Nicotine Nasal Spray The nasal spray delivers nicotine to the nasal mucosa through which it is absorbed. It has the most rapid pharmacokinetics of the currently available nicotine replacement formulations but does not reproduce that of a cigarette.[119] Nasal irritation is very common, particularly when initiating therapy. The recommended dose is one to two sprays per hour for 3 months with a maximum of 80 sprays per day. Because the spray can deliver large amounts of nicotine, it may be particularly effective for heavily addicted smokers. It also likely has a greater risk of nicotine overdose and may have a greater potential to sustain a long-term addiction.

Combination Therapy Various combinations of nicotine replacement may have utility for selected individuals who need higher doses. In particular, combination of a transdermal system with an ad lib modality has been demonstrated to increase quit rates.[97,105,124,128] Because of its increased success, it is recommended by some as initial therapy.[117]

Bupropion Bupropion is approved as an antidepressant, and it is also effective as an aid for smoking cessation.[97,105,129] It is believed to act by potentiating dopaminergic and noradrenergic signaling. The formulations for depression and for smoking cessation have different trade names and dosages, which has clinical relevance. First, an appropriate diagnosis is often required for reimbursement. Second, care is needed not to prescribe bupropion under one name to an individual already taking it under its other name, as overdosage can result.

In clinical trials, bupropion approximately doubles quit rates compared to placebo. Subjects with a history of depression, however, appeared to benefit from bupropion but did not with nicotine replacement, suggesting that bupropion may be a superior initial choice in such individuals. Combination of nicotine replacement with bupropion has been assessed and appears more effective than either agent alone.

The currently recommended dose is 150 mg daily for 3 days, followed by 150 mg twice daily. Because the drug is excreted slowly, steady state-levels are achieved after 6 to 7 days. For this reason, the quit date should be scheduled after a week of therapy so that blood levels are established. As the 150-mg once-daily dose was nearly as effective as the 150-mg twice-daily,[130,131] many practitioners use the lower dose routinely. The appropriate duration of therapy is not established. Clinical trials that formed the basis for approval treated for 7 weeks, although a 12-week course is commonly recommended. With prolonged therapy, there is an increase in secondary quits, and therapy for 1 year resulted in more quits than therapy for 7 weeks.

The drug is generally well tolerated. The most common adverse effects are dry mouth, insomnia, agitation, and headache. In combination with nicotine replacement, an increase in blood pressure also may occur. Bupropion reduces seizure threshold, and a seizure risk of 0.1% has been reported. Because of its reduction in seizure threshold, bupropion is contraindicated among those predisposed to seizures, or with anorexia nervosa or bulimia.

In 2008, the FDA first noted that both bupropion and varenicline (see below) had a "possible association (with) suicidal events."[132] The benefits of smoking cessation were felt to outweigh any potential risks, and the medicines were not withdrawn from the market. In 2016, the FDA removed the black box warning about possible suicidal events from the labels of both bupropion and varenicline following a subsequent large randomized controlled trial showing that the rates of major adverse psychiatric events were similar across all tobacco treatments (including varenicline, bupropion, and NRT) compared with placebo.[133] The rate of adverse psychiatric events was about 6% in patients with underlying psychiatric illness and 2% in otherwise healthy individuals. Thus, regardless of the treatment strategy chosen, it is important for all patients and their caregivers to monitor for possibility of neuropsychiatric symptoms, and patients should be monitored for changes in behavior, hostility, agitation, depressed mood, suicidal ideation, and suicide attempts. Most practitioners make a routine practice of reassessing patients 3 to 7 days after the quit day to both monitor for adverse effects and to provide additional support for the quit attempt. In this context, a second visit has been demonstrated to greatly improve success.[97,105,117]

Varenicline Varenicline is a partial agonist at the $\alpha4\beta2$ nicotinic receptor.[134] As such, it can partially activate the receptor thereby mitigating withdrawal symptoms. In addition, by occupying the receptor, it can prevent nicotine from acting, and thus can reduce the rewarding and reinforcement effects associated with nicotine. This may be particularly important in preventing a lapse from becoming a full relapse once abstinence has been achieved. Both of these effects are supported by evidence from clinical trials.[135–138] Varenicline consistently improves success in quitting compared to placebo by an effect of two- to fourfold.[138] In addition, head-to-head trials have demonstrated superiority compared to bupropion,[133,135,136] as well as to nicotine replacement.[133]

Varenicline is given orally. Usually medicine is started at 0.5 mg once daily for 3 days followed by 0.5 mg twice daily for 4 days and then 1 mg twice daily for 3 months. Individuals who have achieved abstinence at 3 months may have less relapse if therapy is continued for an additional 3 months. A quit date is usually recommended for 1 week after starting medication, but success has been reported with a broader window of quit dates from 1 to 5 weeks that was comparable to a fixed quit rate.[139,140] Gradual scheduled reduction may be helpful during this extended period. This increased flexibility may be an advantage in starting a quit attempt when patients are seen for problems other than smoking cessation.

The most common adverse reactions are nausea, insomnia, visual disturbances, syncope, and skin reactions. The incidence of nausea is reduced with the dose titration described above.[141] The most serious concerns with varenicline have been with psychiatric and cardiovascular side effects. Varenicline had the same boxed warning as bupropion, indicating that patients and their caregivers should be alerted to the possibility of neuropsychiatric symptoms, which, as noted above, has been removed.[132] Consistently, clinical trials have failed to confirm psychiatric adverse effects.[142] A meta-analysis that reported significant increase in cardiovascular events[143] was felt to be methodologically flawed, as it excluded studies with no events.[144] A subsequent meta-analysis that included all available studies found no difference between varenicline and placebo, although a small difference may be present.[144] Based on this information FDA recommended that patients taking varenicline be alert for development of new or worsening symptoms of cardiovascular disease.[145] Varenicline has also been associated with accidental injuries from falls and vehicular accidents.[146] This has resulted in an FDA advisory regarding operating heavy machinery while using varenicline.[147]

Off-Label Agents

A number of drugs have been used “off-label” in smoking cessation programs. Two are briefly considered below.

Clonidine Clonidine is an α-adrenergic agonist active in the CNS that is used to treat hypertension. A number of clinical trials have evaluated its efficacy in smoking cessation and have generally shown a trend toward benefit, although individual trials have generally not been statistically significant, and its use is supported by a meta-analysis.[148] The Department of Health and Human Services (DHHS) guidelines have suggested it can be used by experienced practitioners comfortable with the drug.[97,105] Major adverse effects of clonidine are drowsiness, fatigue, dry mouth, and postural hypotension.

Nortriptyline Nortriptyline is a tricyclic antidepressant that has been evaluated for efficacy in smoking cessation in several studies. Both individual studies and meta-analyses support its benefit as an aid to smoking cessation,[129,149] and it has also been recommended as a possible second-line agent for practitioners comfortable with its use by the DHHS guidelines.[97,105] Major adverse effects of nortriptyline include drowsiness and dry mouth. As with other tricyclics, CNS and cardiovascular effects, including arrhythmias, may occur.

■ Practical Concerns During the Quit Attempt

Smoking cessation entails consideration of a variety of practical concerns, including the general approach to be employed, patient withdrawal symptoms, including cravings and depression, and weight gain, as discussed below.

Approach

As noted above, the first step is to have a patient willing to make a quit attempt. Current practice is to optimize the chance for success with each attempt. In general, this will be achieved with nonpharmacologic support combined with pharmacotherapy. The more active the nonpharmacologic support the greater the likelihood of success. Patients vary, however, in the type of support they will accept.

It is also important to select an appropriate pharmacotherapy. The initial choice is typically customized and depends on several factors including the patient’s prior experience, comorbidities, preferences, and cost. Many practitioners initiate treatment with NRT, because of greater experience and reduced potential for adverse effects. The “patch-plus” regimen that combines a transdermal system with an ad lib formulation is often recommended.[97,105,117] Bupropion may be more appropriate for individuals with a history of depression.[136] Varenicline has the greatest efficacy.[117] The quit date should be linked to the pharmacotherapy: generally, this is 1 week after initiating bupropion or varenicline and on the same day as initiating NRT. Varenicline may offer some flexibility, with a quit date 1 to 5 weeks after starting treatment.[140] A follow-up visit should be scheduled about 10 days after initiating therapy to check for side effects, withdrawal symptoms, and general treatment effectiveness. A follow-up in the immediate post-quitting period is associated with improved success. This may be particularly important for cessation attempts that begin in hospital.[150] Longitudinal follow-up for this chronic relapsing/remitting condition is important.

Withdrawal Symptoms

The first 3 days of abstinence are usually the most difficult. Tobacco withdrawal symptoms (Table 41-2) generally peak during the first 72 hours and then gradually subside over a 3- to 4-week period. These symptoms can include restlessness, anxiety, difficulty concentrating, irritability, frustration, depression, and an almost unrelenting craving for cigarettes. Common suggestions to help smokers cope with these early withdrawal symptoms in addition to NRT can include: (1) Be active. Increased activity may curtail some of the drive to smoke. (2) Use deep breathing exercises. The simplest breathing exercise involves nothing more than extended breath holding followed by slow exhalation through pursed lips. (3) Avoid high-risk situations for smoking during the first 3 weeks of quitting. (4) Use plenty of cinnamon gum or chewable candies. (5) Combat strong urges to smoke: The urge to smoke will go away whether one smokes or not.

Cravings Of all the symptoms associated with nicotine withdrawal, cravings to smoke are the most persistent. Unlike the other symptoms, cravings can also recur long after abstinence is achieved. During the second and third weeks of abstinence, the craving waves

TABLE 41-2 **Nicotine Withdrawal Symptoms (DSM-IV)**

Dysphoric or depressed mood
Insomnia
Irritability, frustration, or anger
Anxiety
Difficulty concentrating
Restlessness
Decreased heart rate
Increased appetite or weight gain

usually occur less frequently, but can sometimes catch smokers off guard because of their unexpected intensity. The decrease in frequency is greater than the decrease in intensity, and cravings can be precipitated months and years after abstinence if precipitated by specific cues. In this context, cravings recapitulate, in some ways, the grief response. Relapse is commonly associated with concurrent alcohol consumption. It is likely that alcohol, and the associated situations in which it is consumed, serves both as a cue leading to craving and decreases the inhibitions that may prevent smoking. Ex-smokers should be aware of these moments of hazard.

Depression At some time during the first 3 months of abstinence, some smokers may experience depression. For many this depression is mild and transient. For a small minority of smokers, quitting smoking may produce a clinical depression that may require antidepressant therapy, counseling, or return to smoking. Depressive symptoms are associated with relapse.[151]

Weight Gain

One of the most disheartening components of quitting smoking is weight gain.[97,105] Rapid weight gain is common during the first 6 to 8 weeks of cigarette abstinence. This is followed by a more gradual increase in weight to roughly 4 kg at 6 months. Average weight gain at 10 years following cessation is 4.4 kg and 5.0 kg for males and females, respectively. The health risks associated with post-cessation weight gain are unknown but are likely surpassed by the health benefits of stopping smoking.

RISKS OF SMOKING CESSATION

Smoking cessation may be associated with some hazards in selected cases. Nicotine and other components of cigarette smoke may have a significant antidepressant effect, and many endogenously depressed individuals may have empirically found smoking helped alleviate their symptoms. Depression is a well-recognized manifestation of the nicotine withdrawal syndrome. At times, this depression can be of major clinical importance. Exacerbations of ulcerative colitis are more common in former smokers and may develop at times long after smoking cessation.[152] These potential adverse effects should not minimize the importance of smoking cessation, but the clinician should be prepared to address them when necessary. Anecdotal reports have suggested that asthma may worsen following cessation. However, smoking generally makes asthmatics worse[153] and induces resistance to the therapeutic effects of inhaled glucocorticoids. Thus, asthma symptoms generally improve with smoking cessation.[154] Some smokers report an increase in cough in the weeks following cessation. However, among individuals with chronic bronchitis, symptoms of cough and sputum production decrease dramatically in the months following cessation.[155,156]

SPECIAL POPULATIONS

Smoking cessation approaches for special populations (e.g., hospitalized patients, those with medical and psychiatric comorbidities, and pregnant patients) are generally the same as for the general population.[157] Smoking cessation treatment can be started in hospital at the time of acute illness.[153] Success depends on adequate follow-up and support. Interestingly, withdrawal symptoms may be particularly mild in hospital, perhaps because there are few options to smoke. Concurrent treatment of individuals hospitalized with psychiatric illness for smoking cessation can be successful and does not compromise treatment of the comorbid psychiatric problem.[157] Treatment of pregnant smokers has been extensively reviewed.[158]

Smoking is a major risk factor for COPD. All three approved forms of pharmacotherapy, NRT,[159] bupropion,[160] and varenicline,[161] have demonstrated efficacy in the COPD population.

HARM REDUCTION

A more controversial approach for smokers who are unwilling or unable to quit at all, is that the health consequences may be partially addressed by reducing the exposure to smoke-derived toxins. This approach, termed "harm reduction," has been the subject of several reviews, including an Institute of Medicine report.[162,163] Four general categories of harm reduction are theoretically possible: (1) administration of agents to counteract the effects of cigarette smoking; (2) smoking reduction; (3) development of less toxic tobacco products; and (4) alternate nicotine delivery systems. This has become particularly important with the rapid increase in prevalence of vaping (see below). It is important to recognize that clear health benefits have not been established for any of these approaches, however, and novel health risks have been clearly associated with vaping.

Since cigarette smoking is thought to cause its effects through pathogenetic mechanisms that are at least partially defined, it is appealing to use such mechanisms as targets for therapeutic intervention. In this regard, antioxidants to ameliorate the oxidant-induced injury caused by cigarette smoke, and protease inhibitors to bolster the antiprotease defenses, are both potential therapies. While conceptually appealing, no data exist to suggest that any such approach is of benefit in continuing smokers.

Pharmacologic support may facilitate reduction in smoking. The observation that most smokers maintain a relatively constant nicotine intake creates the possibility that nicotine replacement can help sustain smoking reduction. Smoking reduction has also been achieved with several formulations of nicotine replacement, and there is some evidence for physiologic benefit. Short-term smoking reduction, facilitated with the use of nicotine polacrilex gum, was associated with improvements in lower respiratory tract inflammation assessed by bronchoscopy and bronchoalveolar lavage in a group of heavy smokers.[164,165] In patients with cardiac disease who reduced smoking, there were measurable improvements in cardiac function that were associated with improved oxygen delivery to the heart due to reduced carbon monoxide.[166]

Reducing the delivery of cigarette smoke toxins while still providing the smoker with a satisfactory cigarette has been pursued by some tobacco companies. This was a major motivation in the development of filtered cigarettes and of low-tar, low-nicotine cigarettes. Unfortunately, these approaches do not reduce, and may actually increase, exposure to smoke-derived toxins. As most smokers maintain constant nicotine intake, many smokers compensate for altered smoke composition by simply smoking more or by changing the way in which they smoke each cigarette.[167,168] By causing an altered smoking strategy, filtered and low-yield cigarettes may actually deliver more toxins.

Many of the cigarette-derived toxins are generated as a result of pyrolysis.[25] As a result, tobacco products that do not burn have the promise to yield fewer toxins. Several cigarette-like devices have been developed with similar goals. Some burn small amounts of processed tobacco together with a carbon heat source to have a taste that more closely resembles a cigarette.[169] Others electrically heat the tobacco. Whether the electronic cigarette will be effective as an alternative to smoking at present remains to be determined (described in more detail below).[163] Because of the rapid and widespread uptake, electronic cigarettes ("e-cigs" or vaping) have been particularly controversial and are discussed in detail in the following section. This led to early reviews and position statements by medical groups including the pulmonary community relating to these products.[170,171] Potential harm-reduction products appear to deliver less toxins in standardized smoking regimes. However, limited data are available on physiologic effects. In one study, a reduction in lower respiratory tract inflammation and airway metaplasia was observed among heavy smokers who switched to a harm-reduction product.[172] Whether such products are associated with health benefits, however, remains to be determined.

Non-burned tobacco products may also have advantages. Moist snuff, which has low nitrosamine content due to its processing, has been widely used for several decades in Sweden. It has been associated with a measurable decrease in a number of tobacco-related diseases among Swedish men compared with cigarettes, but not compared with abstinence.[173–176]

Harm-reduction strategies may have unforeseen problems. Reduced-risk products or smoking reduction strategies may encourage smokers to continue and thus discourage quit attempts. Available data, however, suggest the opposite. Smokers who switch to harm-reduction products or who reduce with pharmacologic support appear to have an increased rate of subsequent quits. It may be that the sense of mastery that comes with the reduction effort helps make smokers “able” to quit. There are other potential hazards. Reduced-risk products, for example, might be particularly appealing for individuals beginning smoking both because they may be easier to smoke and because they are not perceived as having significant risks. Finally, if use of reduced-risk products erodes the social climate that discourages smoking, such products could increase use of conventional cigarettes.

ELECTRONIC CIGARETTES AND VAPING

Electronic cigarettes (EC, also known as “electronic nicotine delivery systems”) are battery-operated devices that heat and aerosolize a liquid solution (an “e-liquid”).[177] E-liquids typically, but not always, contain nicotine. The other main e-liquid components include alcohol-based solvents (propylene glycol and vegetable glycerin) and flavorings.[178] Upon heating, this solution becomes more complex and releases toxic constituents (aldehydes, acrolein), though in much lower quantities compared with combustible cigarettes.[179] The commercialization of ECs developed independently of big tobacco companies,[180] and the products were initially conceived as a harm reduction tool for cigarette smokers.[181] Over time, however, ECs have provoked substantial controversy among tobacco control experts.[182] On one hand, individuals switching completely from cigarettes to ECs might substantially reduce exposure to combustion products and other toxicants.[183] On the other, the products may expose youth and nonsmokers to potent nicotine products that could engender addiction and cause additional health risks.[184,185]

ECs contain three basic components: (1) a battery to provide heat; (2) a metal heating element; and (3) a liquid solution.[177] Within this basic structure, ECs are highly heterogeneous with respect to product design, emissions, toxicity, and nicotine delivery.[186,187] They vary by size, strength of battery, accessibility by the user (i.e., open or closed systems), and the e-liquid used (resulting in countless combinations of nicotine concentration and flavorings).

EC use is known as “vaping.” Vaping is the inhalation of a heated, aerosolized substance. It is distinguished from smoking by its lower temperature and the absence of combustion products in the inhaled aerosol. Although ECs were initially designed for vaping nicotine, it has become recognized more recently that some people use EC devices to consume other substances such as tetrahydrocannabinol (THC), the main psychoactive chemical in marijuana.[188] The implications of these new EC use patterns may have a significant health impact (see “E-Cigarette or Vaping Product Use–Associated Lung Injury,” below).

■ Electronic Cigarettes and Public Health

The net effect of ECs on public health remains a subject of heated debate and is currently unknown. Since its inception, EC use has skyrocketed among youth and young adults, while use of combustible cigarettes has dropped steadily to an all-time low.[189] The long-term implications of this trend raise significant questions and concerns. Does long-term use of ECs produce similar health harms compared with cigarette smoking? Will the uptake of ECs lead to more or fewer combustible cigarette smokers in the future? Will a new generation of young people develop addiction to nicotine?

A comprehensive scientific review of ECs was published in 2018 by the National Academy of Sciences.[177] The data to date provide conclusive evidence that most EC products emit toxic substances, that EC toxicity varies substantially among products and individual use patterns, that accidental high-dose exposure to e-liquids or faulty EC batteries can be highly hazardous, and that completely substituting ECs for regular cigarettes reduces user exposure to many toxicants and carcinogens.[177] Substantial evidence suggests: (1) that nicotine exposure from ECs can induce dependence and may be similar to combustible cigarettes in some users, (2) that exposure to toxic substances is significantly lower compared with combustible cigarettes, (3) that EC aerosol constituents can induce endothelial dysfunction, oxidative stress, and DNA damage, (4) that youth who use ECs may be at higher risk of subsequent combustible cigarette smoking, and (5) that completely switching to ECs from combustible cigarettes may reduce short-term adverse health outcomes in several organ systems.

Despite the existing evidence, many key questions remain unanswered. Do ECs lead to pulmonary, cardiovascular, and oncologic diseases? If so, how does disease onset, probability, and severity compare with chronic cigarette smoking? Will the presence of ECs ultimately reduce or increase combustible cigarette use at the population level? How addictive are ECs compared with combustible cigarettes? What will this mean for public health? These questions will need to be answered over the next several decades through careful investigation.

■ Electronic Cigarettes in Smoking Cessation and Tobacco Harm Reduction

The overwhelming majority of tobacco-related harm derives from cigarette smoking.[190] Although smokeless tobacco consumption carries health risk, it is substantially less harmful than smoking.[191,192] Places such as Sweden, which has a substantial number of snus (smokeless tobacco) users, has the lowest rate of lung cancer among developed countries.[193] The idea that ECs use can promote harm reduction is appealing, at least in theory. The idea is to substitute smoke inhalation with the substantially less toxic EC aerosol, which is devoid of combustion products and has lower amounts of known carcinogens compared with smoke.[179,183,194,195] The concept is similar to providing methadone, buprenorphine, or clean needles to people who inject heroin. These steps do not entirely eliminate opioid-related risk, but they reduce risk substantially.[196–198] Much of the resistance to EC use as a harm reduction strategy arises from a lack of definitive data showing effectiveness and improved outcomes in the adult smoker population, as well as concerns over effects on youth and other nonsmokers. These data, if they exist, will not be available for many years, given the relatively short duration that ECs have been in widespread use. Thus, harm reduction from EC use remains a theoretical possibility to date but remains to be proven.

There is evidence suggesting that ECs use can help some people to stop combustible cigarette smoking, both at the population and individual levels.[199–201] Although unclear whether a causal effect, smoking rates have declined more quickly in the United States since the introduction of ECs into commercial markets, possibly indicating a substitution effect (i.e., people choosing to use ECs instead of cigarettes).[202] Early clinical trials examined ECs in both motivated and unmotivated cigarette smokers. These studies found smoking quit rates similar to or non-statistically higher than the nicotine patch, as well as reductions in cigarettes smoked per day.[203,204] Study limitations included low overall smoking quit rates and the use of early-generation EC products, which likely limited the statistical power necessary to observe differences between groups.

A significant follow-up study, which is the most important to date, is a multicenter trial of 886 smokers conducted throughout the United Kingdom that directly compared second-generation ECs to traditional combination nicotine replacement (e.g., nicotine patch, gum, lozenge).[201] Both groups received behavioral counseling as part of usual care. The key study finding was that those randomized to the EC group were nearly twice as likely to achieve smoking abstinence at week 52 compared with the NRT group (18.0% vs. 9.9%; relative risk, 1.83; 95% confidence interval, 1.30–2.58), with no differences in adverse events between groups. However, 80% of subjects in the EC group were still using their EC product at the end of the study, indicating that long-term nicotine use via EC was a key factor in maintaining smoking abstinence. As noted, the long-term health effects of chronic EC use remain unclear.

■ E-Cigarette or Vaping Product Use–Associated Lung Injury (EVALI)

In mid-to-late 2019, the U.S. Centers for Disease Control and Prevention (CDC) began receiving reports of acute lung injury cases clinically resembling the acute respiratory distress syndrome (ARDS) (see Chapter 140) occurring in patients who reported a history of EC vaping and had no other clear cause for lung injury.[205] The clinical syndrome commonly affected young people and resembled a systemic illness that typically resulted in fever, dyspnea, nausea/vomiting, pulmonary infiltrates, and acute respiratory failure that sometimes required mechanical ventilation.[206–208] A wide range of pathologic patterns were reported, and the presence of lipid-laden macrophages with oil red O staining was common.[207–209] Anecdotally, corticosteroids seemed to hasten recovery.

The discovery of this syndrome led to intense scrutiny and reporting of the new disease phenotype, subsequently named “e-cigarette or vaping product use–associated lung injury” (EVALI). A variety of ECs and vaping products were reported, making it initially difficult to pinpoint a specific cause of the epidemic. Importantly, the first case series published involving patients in Illinois and Wisconsin found that 84% of EVALI cases involved vaping of tetrahydrocannabinol (THC) oils in EC devices.[206] THC is the main psychoactive chemical in marijuana[210] and had not been previously widely recognized as a substance consumed via EC vaping. A subsequent investigation by CDC and FDA revealed that bronchoalveolar lavage samples from EVALI patients contained vitamin E acetate, a cutting agent used to dilute THC-containing e-liquids.[211] Follow-up investigations into the used products from EVALI cases seized by law enforcement revealed high proportions of illicit THC e-liquids containing vitamin E acetate.[212] These discoveries provided strong support that EVALI was driven predominantly by vitamin E acetate–contaminated THC e-liquids, although other EC-related chemical causes of acute lung injury could not be definitively ruled out.

■ Practical Considerations for Clinicians Treating Patients Who Use E-Cigarettes

The clinician is very likely to encounter EC use among patients in clinical settings.[213] The optimal approach to these patients, many of whom may be current or former cigarette smokers and have other medical and psychiatric comorbidities,[214] can be challenging. On one hand, it is clearly best for patients to abstain from inhalation of all toxic substances, including combustible cigarettes and ECs; this is certainly a message that physicians want to convey strongly to patients. Yet, for former smokers, EC use may prevent relapse into combustible smoking and might reduce harm.[201] The severe health harms of continued cigarette smoking are well established.[190] Furthermore, while there have been tested approaches to smoking addiction, the optimal approach to treating vaping addiction is unknown.

Thorough social and past medical histories will help identify the patient’s level of risk, in addition to other comorbidities (i.e., mental health and other substance use disorders) that may influence the course of nicotine addiction. Routine screening for tobacco product use should include a specific question about the use of ECs and vaping. Developing an understanding of the reasons for use, the duration and frequency of use, the types of products (e.g., nicotine content, flavorings, and use of other drugs, such as THC), and where the products were obtained (e.g., authorized retailers or from informal sources such as friends) is helpful. It is important to understand whether there is dual use of combustible cigarettes and ECs and whether ECs are being used to reduce combustible use or to supplement nicotine consumption in places where smoking is forbidden. Assessing motivation to discontinue use provides an opening to encourage abstinence and trials of other treatments, such as transdermal nicotine replacement, varenicline, bupropion, and behavioral counseling.

Advice should be framed carefully, as EC use in this population may prevent relapse into cigarette smoking. It is important to note that long-term abstinence rates from cigarette smoking are low, especially for those who do not achieve abstinence for at least 3 months.[215] Thus, the population of EC users (particularly those with past or present cigarette smoking history) may represent a group with a higher level of nicotine dependence. While cessation of all inhaled substances should be encouraged, permanent and complete cessation from combustible products should be highly prioritized. If the patient is solely using ECs (and not using combustible products), it is useful to explore whether they wish to stop vaping as well. Despite a lack of evidence of effectiveness in people who vape, the combination of behavioral and pharmacologic treatments, which is the standard of care for the treatment of cigarette smoking addiction, is a reasonable starting point. It is not clear whether attempting to reduce the nicotine level in e-liquids used is a beneficial strategy to promote vaping cessation, since individuals might engage in compensatory puffing behavior (e.g., bigger or longer puffs) to maintain similar nicotine intake.[216] Longitudinal support to monitor progress and try different approaches as needed will likely be required in these patients.

■ What Is the Future of E-Cigarettes?

EC use will continue into the 21st century, alongside combustible cigarettes and other tobacco products. The economic growth of ECs since their inception has been staggering, yet the global demand for the products remains only a tiny fraction of the combustible cigarette market. Future trends in EC use may depend largely upon regulatory efforts, which, in turn, will be affected by public perception and opinion about the products’ relative harms and benefits. Scientific discovery will drive part of this discussion, but economic and political factors also will play a significant role.

A natural experiment in EC regulation may be emerging, as the United Kingdom has widely promoted EC use among its adult smokers for harm reduction, while other countries, such as the United States, have cracked down on the EC market more strongly in an effort to protect youth. It will be critical to understand how these different approaches affect tobacco use and health at the population level. Longitudinal trends in both combustible and noncombustible tobacco use, as well as health effects in both youth and adult populations, will provide needed insight into the effects of ECs.

CONCLUSION

Cigarette smoking is a complex social and medical issue. The physician has a particularly important role in curbing smoking. Not only must the physician participate in efforts to reduce smoking as a citizen, but as a protector of public health and a possessor of specific expertise in healthcare matters, the physician must take an active role in health promotion. Such a role includes discouraging smoking and vaping initiation among younger patients, encouraging and assisting smoking patients to quit, and participating in social efforts designed to reduce smoking at various levels.

For individuals who are smokers, the clinician needs to approach smoking as a chronic relapsing disorder for which a range of effective treatments are available. These include nonpharmacologic and pharmacologic therapies. Optimal results can be achieved using a combined approach.

CHAPTER 42

Rehabilitation in Chronic Obstructive Pulmonary Disease and Other Respiratory Disorders

Andrew L. Ries
Duc M. Ha

INTRODUCTION

Rehabilitation for patients with chronic lung diseases is well established as a means of enhancing standard pharmacologic and other therapies in controlling and alleviating symptoms and optimizing functional capacity.[1–5] The primary goal of any rehabilitation program is to restore the patient to the highest possible level of independent function. This goal is accomplished by helping patients and significant others learn more about the underlying disease, treatment options, and coping strategies. Patients are encouraged to participate actively in providing their own health care, become more independent in daily activities, and be less dependent on health professionals and expensive medical resources. Rather than addressing solely reversal of the disease process, rehabilitation focuses on improving disability from disease.

Historically, pulmonary rehabilitation strategies were developed and used primarily for patients with chronic obstructive pulmonary disease (COPD). However, pulmonary rehabilitation has also been applied successfully to patients with other chronic lung conditions, including interstitial lung diseases, asthma, cystic fibrosis, bronchiectasis, pulmonary hypertension, and thoracic cage abnormalities.[3,5–7] Also, among patients with lung cancer, rehabilitation prior to resectional surgery improves exercise capacity and may reduce perioperative complications and length of hospital stay.[8] Following surgery, rehabilitation can mitigate the adverse effects of treatment and improve physical function and symptom control, especially if initiated early.[9–12] Patients with advanced lung cancer can also experience improvements in exercise capacity with training.[13]

Pulmonary rehabilitation has been used successfully in the evaluation and preparation of patients for surgery, such as lung transplantation and lung volume reduction surgery, and in maximizing recovery after surgery.[14–16] Pulmonary rehabilitation has also been used to facilitate patient recovery from acute processes such as acute lung injury, or exacerbations of chronic lung disease requiring mechanical ventilation or acute hospital care. The 2020 worldwide COVID-19 pandemic highlights the needs and potential benefits of pulmonary rehabilitation for the large number of patients recovering from lung injury.[17]

Pulmonary rehabilitation is appropriate for any patient with stable lung disease who is disabled by respiratory symptoms. Even patients with advanced disease may benefit if they are selected appropriately and realistic goals are set.

This chapter defines pulmonary rehabilitation and outlines issues related to patient selection and evaluation. There is also discussion of key components of a pulmonary rehabilitation program, results and benefits of pulmonary rehabilitation, the use of pulmonary rehabilitation in various conditions and settings, and, finally, the role of rehabilitation as an adjunct to lung surgery.

DEFINITION

In 2013, the American Thoracic Society and European Respiratory Society adopted the following definition:

> "Pulmonary rehabilitation is a comprehensive intervention based on a thorough patient assessment followed by patient-tailored therapies, which include, but are not limited to, exercise training, education, and behavior change, designed to improve the physical and psychological condition of people with chronic respiratory disease and to promote the long-term adherence of health-enhancing behaviors."[3]

This definition highlights three important features of successful rehabilitation. First, the program is *multidisciplinary.* Pulmonary rehabilitation programs utilize expertise from various healthcare disciplines that is integrated into a comprehensive, cohesive program tailored to the needs of each patient. Second, the program is tailored to the *individual.* Patients with disabling lung disease require individual assessment of needs, individual attention, and a program designed to meet realistic individual goals. Third, the program addresses *multidimensional health issues* including physical, psychological, and social function as well as healthcare utilization.

The team of healthcare professionals in pulmonary rehabilitation may include physicians, nurses, respiratory and physical therapists, mental health professionals, exercise specialists, and others with appropriate expertise. The specific team make-up depends upon the resources and expertise available, but it usually includes at least one full-time staff member. Responsibilities of team members generally cross disciplines.[18]

Within this general framework, successful pulmonary rehabilitation programs have been established in both outpatient and inpatient settings and with different formats. A key to success is a dedicated, enthusiastic staff that is familiar with respiratory problems and can relate well to pulmonary patients and motivate them.

PATIENT SELECTION

Any patient with symptomatic chronic lung disease is a candidate for pulmonary rehabilitation (Table 42-1).[19] Appropriate patients are aware of disability from their disease and motivated to participate actively in their own care to improve their health status. Patients with mild chronic disease may not perceive their symptoms to be severe enough to warrant a comprehensive care program. On the other hand, patients with severe disease who are bed bound may be too limited to benefit greatly.

Criteria based on arbitrary lung function parameters or age alone should not be used in selecting patients.[4] Pulmonary function alone is not a good predictor of symptoms, function, or improvement after rehabilitation. Chronic lung disease is commonly associated with systemic features that contribute to functional limitations and may

TABLE 42-1 Patient Selection Criteria for Pulmonary Rehabilitation

Symptomatic chronic lung disease
Stable on standard therapy
Functional limitation from disease
Relationship with primary care provider
Motivated to be actively involved in and take responsibility for own health care
No other interfering or unstable medical conditions
No arbitrary lung function or age criteria

benefit from rehabilitation.[20] In general, selection should be based upon a person's disability from their disease, potential for improvement, and motivation to participate actively in a comprehensive self-care program. Also, pulmonary rehabilitation is not a primary mode of therapy. Patients should be stabilized on standard medical therapy and should not have other disabling or unstable conditions that might limit their ability to participate fully in the program and to concentrate on the necessary tasks.

The ideal patient for pulmonary rehabilitation, then, is one with functional limitation from moderate to severe lung disease who is stable on standard therapy, not distracted or limited by other serious or unstable medical conditions, willing and able to learn about his or her disease, and motivated to devote the time and effort necessary to benefit from a comprehensive care program.

PATIENT EVALUATION

The initial step is screening patients to ensure appropriate selection and to set realistic individual and program goals. The evaluation process includes the following components: interview, medical evaluation, psychosocial assessment, diagnostic testing, and goal setting (Table 42-2).

Interview

The screening interview is an important first step. It serves to introduce the patient to the program, review the medical history, and identify psychosocial problems and needs. Family members and significant others should be included. Communication with the primary care provider is important to establish the vital link for the rehabilitation staff to clarify medical questions prior to the program and facilitate subsequent recommendations. Care and attention in this initial evaluation helps in setting goals compatible with everyone's expectations as well as appropriate programmatic objectives.

Medical Evaluation

Reviewing medical history helps to identify the patient's lung disease and assess its severity. Other medical problems that might preclude or delay participation may be identified. Available laboratory data should be reviewed, including pulmonary function and exercise tests, rest and exercise arterial blood gas measurements, chest radiographs, electrocardiogram, and pertinent blood tests. Program staff can then determine the need for any additional information or action before the program begins.

Psychosocial Assessment

Successful rehabilitation requires attention not only to the patient's physical problems but also to psychological, emotional, and social issues. Patients with chronic illnesses experience psychosocial difficulties as they struggle to deal with symptoms they may not fully understand.[21]

Neuropsychological impairment is common in patients with chronic lung diseases and cannot be accounted for solely on the basis of age, depression, or organic disease. Commonly, such patients become depressed, frightened, anxious, and more dependent on others to care for their needs. Progressive dyspnea is a frightening symptom and may lead to a vicious "fear–dyspnea" cycle: With progressive disease, less exertion results in more dyspnea, which produces more fear and anxiety, which, in turn, lead to more dyspnea. Ultimately, the patient avoids any physical activity associated with both of these unpleasant symptoms.

In addressing these problems, the initial evaluation should assess the patient's psychological state and pay attention to "psychosocial clues" that may be apparent during the screening interview (e.g., level of family and social support, the patient's living arrangement, activities of daily living, hobbies, and employment potential). Important clues in initial interviews to the patient's emotional state may be evident in nonverbal communication, such as facial expression, physical appearance, handshake, and personal space (distance between individuals when conversing). Cognitive impairment that may limit the patient's ability to participate fully in the rehabilitation program may be identified. Family members and significant others may provide valuable insight and should be included in the screening process and program whenever possible.

Diagnostic Testing

Planning an appropriate rehabilitation program requires accurate, current information. The complexity of the testing procedures performed depends upon individual patient and program goals as well as the facilities and expertise available.

Pulmonary function testing is used to characterize lung disease and quantify impairment. Spirometry and lung volume measurements are most useful. Other tests (e.g., diffusing capacity, maximal respiratory pressures to assess muscle strength) can be added as needed.

Exercise testing helps to assess the patient's exercise tolerance and to evaluate changes in arterial blood gases (e.g., hypoxemia or hypercapnia) with exercise.[22,23] This may also uncover coexisting diseases (e.g., heart disease). The exercise test is also used to establish a safe and appropriate prescription for subsequent training.

Maximal exercise of patients with chronic lung disease is limited largely by their breathing reserve, although chronic lung diseases are increasingly recognized as being associated with systemic effects that may also contribute to exertional symptoms (e.g., muscle fatigue). Simple pulmonary function tests such as spirometry can be used to estimate a patient's capacity for sustained breathing (maximal ventilation) during exercise. The forced expiratory volume in 1 second (FEV_1) is most useful in this regard. However, lung function only provides an estimate of an individual patient's maximum work capacity. Exercise tolerance depends also on the patient's perception and tolerance of the subjective symptom of breathlessness. Therefore, it is important to exercise patients to assess their physical function and symptom tolerance.

Exercise evaluation for rehabilitation is most easily performed with the type of activity planned for training (e.g., treadmill for a walking training program). Laboratory exercise testing is most commonly performed using either (1) rapid, progressive, incremental levels to a symptom-limited maximum or (2) defined steady-state levels.[22,24] The former is most useful for determining exercise tolerance and the limitations to maximum performance. The latter may be preferred for assessing training prescriptions. Simpler exercise tests, such as the 6-minute walk test, have been used increasingly in recent years to measure exercise tolerance outside of a laboratory setting.[25] These timed distance walk tests measure the maximum distance a person can walk within a defined period (e.g., 6 minutes). Such tests have the advantage of requiring less equipment and technical expertise; however, attention must be paid to the details of testing procedures because variations in factors such as the walking course, patient instructions, encouragement during tests, use of oxygen or monitoring devices, and number of tests performed will influence the results. Also, these tests do not provide the detailed physiologic data typically included in more formal laboratory exercise tests.

Measurement of arterial blood gases at rest and during exercise is important because of the frequent but unpredictable occurrence of exercise-induced hypoxemia.[26] Arterial blood gas sampling during exercise makes testing more complex. The noninvasive estimate of arterial oxygen saturation by cutaneous (e.g., pulse) oximetry is useful for continuous monitoring, but it has limited accuracy (95% confidence limits, ± 4%–5%).[27]

Goals

After a patient's medical, physiologic, and psychosocial state have been evaluated, specific goals should be set that are compatible with his or her disease, needs, and expectations. Goals should be realistic in light of the program objectives. Family members and significant others should be included so that all understand what can and cannot be achieved. Programs should evaluate individual patients to document changes before and after pulmonary rehabilitation with standardized outcome measures of exercise tolerance (e.g., 6-minute walk distance) and symptoms (e.g., dyspnea) or health status (e.g., health-related quality of life).

PROGRAM CONTENT

Comprehensive pulmonary rehabilitation programs typically include several key components: education, instruction in respiratory and chest physiotherapy, psychosocial support, and exercise training (Table 42-2). Often, the various components are provided simultaneously; for example, during an exercise session, a patient may learn and practice breathing techniques for symptom control while being encouraged and supported by staff or other patients. Although there is no consensus regarding the optimal duration of a pulmonary rehabilitation intervention, typical programs last 6 to 12 weeks with 2 to 3 sessions per week, each session including several hours of supervised exercise training and individual or group education and psychosocial interventions.

Education

Successful pulmonary rehabilitation depends upon an understanding of lung disease and active involvement by patients and important others in providing social support. Education is an integral component; even patients with severe disease can gain a better understanding of their disease and learn specific means to deal with problems. Instruction can be provided individually or in small groups, but it should be adapted to different learning abilities. Topics discussed commonly include normal lung function, chronic lung disease, medications, nutrition, travel, stress reduction and relaxation, reasons to call the physician, and planning a daily schedule. Individual instruction and coaching may be provided on the use of respiratory therapy equipment and supplemental oxygen, breathing techniques, bronchial drainage, chest percussion, energy-saving techniques, and self-care tips. The general philosophy is to encourage patients to assume responsibility for their own care and become partners with their physician in providing the care.[28]

Despite the importance of education, it is unlikely that increased patient knowledge alone will lead to improved health status. It is more difficult to change attitudes and behaviors. Patients require specific, individualized treatment strategies, instruction, and reinforcement. Thus, education is a necessary but not sufficient component of pulmonary rehabilitation.

Respiratory and Chest Physiotherapy Techniques

Patients with chronic lung disease use, abuse, and are confused about respiratory and chest physiotherapy techniques. In pulmonary rehabilitation, each patient's needs for respiratory care techniques should be assessed and instruction provided in proper use. These techniques may include chest physiotherapy to control secretions, breathing retraining techniques to relieve and control dyspnea and improve ventilatory function, and proper use and care of respiratory equipment including nebulizers, metered dose inhalers, and supplemental oxygen.

Bronchial Hygiene

Patients with chronic lung diseases frequently have abnormal lung clearance mechanisms that increase problems with retained secretions and infection. Therefore, rehabilitation programs teach a variety of chest physiotherapy techniques for secretion control (e.g., coughing, postural drainage, chest vibration, and percussion). These are important for patients who experience excess mucus production during exacerbations as well as for those with chronic sputum production. The use of mucolytic agents to reduce viscosity of secretions is of questionable benefit.[29,30]

Breathing Retraining Techniques

Pulmonary rehabilitation typically includes instruction in breathing techniques, such as diaphragmatic and pursed lips breathing—techniques aimed at helping patients relieve and control breathlessness, improve their ventilatory pattern (i.e., slowed respiratory rate and increased tidal volume), prevent dynamic airway compression, improve respiratory synchrony of the abdominal and thoracic musculature, and improve gas exchange.[31] Review of studies evaluating these techniques indicates that improvement in symptoms (e.g., dyspnea) is a more consistent finding than are measurable changes in physiologic parameters. The diaphragmatic breathing technique is a maneuver in which the patient consciously coordinates abdominal wall expansion with inspiration and slows expiration through pursed lips. The primary effect is to slow respiratory rate and increase tidal volume. Pursed-lip breathing is commonly taught to pulmonary patients, particularly those with COPD. This technique was observed by Laennec as early as 1830 and advocated as a physical exercise for pulmonary patients in the early part of the twentieth century. As a maneuver assumed naturally by many patients with respiratory disease, pursed-lip breathing is characterized by tensing the lips and narrowing the mouth opening during expiration. The aim is to slow expiration and maintain positive airway pressure to "stent the airways open" and prevent collapse.[32]

Oxygen

When chronic oxygen therapy is required, available delivery methods should be reviewed to help select the best system for the patient's needs. Supplemental oxygen is beneficial for patients with severe resting hypoxemia. Long-term continuous oxygen therapy has been clearly shown to improve survival and reduce mortality and morbidity in hypoxemic patients with COPD.[33,34] The benefits of supplemental oxygen for nonhypoxemic patients or those with intermittent hypoxemia (e.g., during exercise or sleep) are less clearly defined. Although continuous oxygen therapy is feasible and safe, maintaining patients on supplemental oxygen presents several challenges. Handling equipment is particularly difficult for physically disabled and frail patients. Therefore, it is important to assess each person's oxygen needs and provide appropriate instruction.[35,36]

Several new developments have improved the efficiency of gas delivery systems and patient compliance with continuous oxygen therapy. Liquid oxygen provides more gas with less weight than tanks of compressed gas, particularly in portable systems. Oxygen-conserving devices may increase the efficiency of delivery, reducing flow requirements and prolonging the life span of portable gas sources. Transtracheal oxygen delivery may help to improve compliance and avoid problems with nasal catheters; however, patients must be instructed carefully in caring for the catheter.[37]

■ Exercise

Exercise is important in pulmonary rehabilitation.[38] Considerable evidence supports favorable responses to exercise training in patients with chronic lung diseases.[5,36] Benefits are both physiologic and psychological. Patients may increase their maximum capacity and endurance for physical activity, even though objective measures of lung function do not usually change. Patients may also benefit from learning to perform physical tasks more efficiently. Exercise training provides an ideal opportunity for patients to learn their capacity for physical work and use and practice methods for controlling dyspnea (e.g., breathing and relaxation techniques). Of all the components in a comprehensive pulmonary rehabilitation program, exercise is probably the most costly and labor-intensive, considering the personnel, equipment, and expertise required. Principles of exercise for patients with lung disease differ from those based on normals or other patient populations because of differences in the limitations to exercise and the problems encountered in training.

Many approaches have been used to train the person with chronic lung disease. To be successful, the program should be tailored to the individual's physical abilities, interests, resources, and environment. For general application, techniques should be simple and inexpensive. As in normals and other patients, benefits are largely specific to the muscles and tasks involved in training. Patients tend to do best with activities and exercises for which they are trained. Walking programs are particularly useful. They have the added benefit of encouraging patients to expand social horizons. In inclement weather, many can walk indoors (e.g., at shopping malls). Other types of exercise (e.g., cycling, swimming) also are effective. Patients should be encouraged to incorporate regular exercise into daily activities they enjoy (e.g., golf, gardening). Since many persons with chronic lung disease have limited exercise tolerance, emphasis during training should be placed on increasing endurance. Changes in endurance with rehabilitation are often greater than changes in maximal exercise tolerance and allow patients to become more functional within their physical limits. Increase in maximum exercise is also possible as patients gain experience and confidence. Resistive training is also used commonly in rehabilitation and can lead to significant increases in muscle strength that are important for many activities of daily living.[36,39]

■ Exercise Prescription

Selecting a training target based upon a predetermined percentage of predicted maximal heart rate or ($\dot{V}O_2$) is a well-established practice for normals or patients without underlying pulmonary disease. However, in patients with chronic lung diseases, the best method of choosing an appropriate training prescription is less clearly defined. Exercise tolerance in pulmonary patients is typically limited by maximal achievable ventilation and breathlessness. Such patients frequently do not reach their limits of cardiac or peripheral muscle performance.

Much controversy exists regarding the appropriate training intensity target for patients with chronic lung disease. Use of a target heart rate has been advocated by some, although it is recognized that such a target may not be reliable for patients with more severe disease. Many patients with lung disease can be trained at a high percentage of maximal exercise tolerance, with work levels approaching or even exceeding the maximal level reached on the initial exercise test. In a study of 52 patients with moderate to severe COPD, patients were able to perform endurance exercise testing at an average workload of 95% of their baseline maximum.[40] After 8 weeks of training, these patients were training at 86% of the baseline maximum. In fact, many patients with severe COPD were exercising at levels exceeding their baseline maximum. In another study that examined 59 patients with moderate to severe COPD who trained at levels near their ventilatory limits, a mean peak exercise ventilation of 100% of measured maximal voluntary ventilation was achieved after 12 days of training and at 3 months of follow-up.[41] These findings suggest that even patients with advanced disease can be trained successfully at or near maximal exercise levels.

Based on the findings noted previously, some pulmonary rehabilitation programs define exercise targets and progression during training more by symptom tolerance than heart rate, work level, or other physiologic measurements. Ratings of perceived symptoms (e.g., breathlessness) help teach patients to exercise to "target" levels of breathing discomfort. A typical approach is to begin training at a level that the patient can sustain with reasonable comfort for several minutes and then to increase the time or exercise level according to symptom tolerance. Patients are encouraged to exercise daily and increase exercise duration up to 15 to 30 min of continuous activity. This graduated program helps patients to achieve a goal of improved tolerance for tasks of daily living, which often require a period of sustained activity.

■ Blood Gas Changes

A major problem in planning a safe exercise program for patients with lung disease is the potential for worsening of hypoxemia with exercise. Patients who are not hypoxemic at rest may develop changes in arterial oxygenation that cannot be predicted reliably from resting measurements of pulmonary function or gas exchange.[26] Normal individuals do not become hypoxemic with exercise. In patients with obstructive lung disease, Pa_{O_2} changes unpredictably during exercise. In patients with mild COPD, Pa_{O_2} typically does not change with exercise; in fact, it may even improve. However, in patients with moderate to severe COPD, Pa_{O_2} may increase, decrease, or remain the same. Patients with interstitial lung disease commonly develop worsening oxygenation with exercise.

Based on these observations, it is important to evaluate a patient's oxygenation status both at rest and during exercise. Such testing is also used to prescribe oxygen therapy at rest and with physical activity. With the availability of convenient, portable systems for ambulatory oxygen delivery, hypoxemia is not a contraindication to safe exercise training.

■ Other Types of Exercise

Exercise programs for pulmonary patients typically emphasize lower extremity training (e.g., walking or cycling). Since exercise conditioning is largely specific to the muscles and tasks involved in training, other forms of exercise may be particularly valuable for persons with chronic lung diseases.

Upper Extremity Training

Many patients with chronic lung disease report disabling dyspnea with daily activities involving the upper extremities (e.g., lifting, grooming) at much lower work levels than with the lower extremities. Upper extremity exercise is accompanied by a higher ventilatory demand for a given level of work than is lower extremity exercise. Given the aforementioned muscle specificity of training, upper extremity exercises may be important in helping pulmonary patients cope better with common daily activities.[42]

Ventilatory Muscle Training

The potential role of ventilatory muscle fatigue as a cause of respiratory failure and ventilatory limitation in patients with chronic lung disease has stimulated attempts to train the ventilatory muscles. Techniques of isocapnic hyperventilation, inspiratory resistive loading, and inspiratory threshold loading have been shown to improve function of the respiratory muscles in both normals and patients. In normals, respiratory muscle function does not limit exercise tolerance; therefore, specific respiratory muscle training is unlikely to be of clinical benefit. In patients with COPD, the patient group most extensively studied, improvement in general exercise performance from ventilatory muscle training alone has not been demonstrated consistently. Thus, the role of respiratory muscle training as a routine component of pulmonary rehabilitation has not been clearly established.

■ Psychosocial Support

An essential component of pulmonary rehabilitation is psychosocial support, the goal of which is to help patients combat progressive feelings of hopelessness and an inability to cope with chronic, progressive disease.[21] Depression is common in patients with chronic pulmonary disorders, as are anxiety (especially anxiety over dyspnea), denial, anger, and isolation. Patients become sedentary and dependent upon family members, friends, and medical services to provide for their needs. Excessive concern over other physical problems and psychosomatic complaints arise. Sexual dysfunction and fear are common and represent often unspoken consequences of chronic lung disease. Patients may also demonstrate cognitive and neuropsychological dysfunction, possibly related to or exacerbated by the effects of hypoxemia on the brain.

Psychosocial support is provided best by a warm and enthusiastic staff who can communicate effectively with patients and devote the time and effort necessary to understand and motivate them. Family members and significant others should be included in activities so that they can understand the disease and help the patient cope. Support groups also are effective. Patients with severe psychological disorders may benefit from individual counseling and therapy. Psychotropic drugs should generally be reserved for patients with more severe psychological dysfunction.

BENEFITS OF PULMONARY REHABILITATION

Pulmonary rehabilitation is an established effective management strategy for people with COPD that improves functional and maximal exercise capacity and health-related quality of life.[1–3,5] It also effectively alleviates dyspnea and fatigue, enhances the sense of disease control, and improves emotional functioning (Table 42-3). Traditionally, pulmonary rehabilitation is thought to be beneficial only for patients with stable disease. However, in more recent years, rehabilitation has been demonstrated to have an important role for those recovering from acute disease. In a landmark study, Man and coworkers recruited 42 patients within 10 days of discharge from hospitalizations for COPD exacerbations to undergo an 8-week pulmonary rehabilitation program.[43] Compared with usual care, patients who underwent pulmonary rehabilitation experienced large and clinically meaningful improvements in exercise capacity and health-related quality of life. Subsequent trials have replicated these findings, additionally demonstrate benefits towards reducing hospital readmission (Fig. 42-1) and possibly mortality risks.[44–47] The mechanisms for benefits are multifactorial and include mitigating hospital-associated disability and reversing the negative consequences of disease exacerbation on muscle and cognitive function, comorbidity control, and self-efficacy.[48] Therefore, pulmonary rehabilitation is an important therapy that spans across the life course and disease severity for people with COPD, to reduce morbidity and possibly mortality.

TABLE 42-3 Results of Pulmonary Rehabilitation

Decreases in
Medical resource utilization (e.g., hospitalizations, emergency room visits)
Respiratory symptoms (e.g., breathlessness)
Psychological symptoms (e.g., depression, fear)
Increases in
Quality of life
Physical activity
Exercise tolerance (endurance, maximal level of activities of daily living, strength)
Knowledge
Independence
Return to work possible
No change in lung function
Possible prolonged survival

Benefits and cost savings associated with pulmonary rehabilitation have been demonstrated not only in highly specialized centers, but also in community-based practice settings.[3,5,49] A collaborative study of 647 patients in 10 centers in California reported significant improvements in dyspnea and health-related quality of life along with substantial reduction in measures of healthcare utilization over 18 months of follow-up (Fig. 42-2).[50] Similar findings with a reduction in hospital and intensive care unit days in the year after compared with the year before pulmonary rehabilitation were reported by a consortium of 11 centers in Connecticut and New York in 128 patients.[51] Overall, among treatment options for patients with COPD, pulmonary rehabilitation has been shown to be very cost-effective (Fig. 42-3).[52]

PULMONARY REHABILITATION AND LUNG SURGERY

In recent years, surgical options for patients with severe, disabling lung disease have expanded. Lung surgery in these patients represents new challenges and may further compromise already reduced lung function. Pulmonary rehabilitation has been found to be a valuable adjunct in preparing the patient for surgery or in postsurgery recovery.

■ Lung Transplantation

Pulmonary rehabilitation is recommended and used commonly in both the preoperative and postoperative phases of lung transplantation programs.[14] Although the general strategies of rehabilitation may be similar, the individual and program goals and specific program components differ.

■ Pretransplant Rehabilitation

Patients with advanced lung disease who are candidates for lung transplantation are usually evaluated by the transplant team and then referred for pulmonary rehabilitation after their transplant candidacy is approved. Rehabilitation staff evaluate the patient to assess needs and plan an appropriate program that can be maintained throughout a waiting period, which may last months to

years. Since these patients have advanced disease with limited life expectancy, the goals in the preoperative period differ from those that typically apply to rehabilitation in chronic lung disease.

The overall goals of pretransplant pulmonary rehabilitation are to maintain function, monitor disease progression, prevent complications, provide education about the underlying lung disease and lung transplantation, and offer psychosocial support for patients and families in coping with the stresses of waiting for a potentially life-saving procedure. Although patients may have some initial improvement in exercise tolerance or endurance as they begin rehabilitation, the primary goal for these patients is to maintain mobility and exercise capacity. Exercise sessions also provide an excellent means to monitor disease progression and to detect, at an earlier stage, problems that commonly occur (e.g., increased breathlessness or reduced arterial oxygenation with exercise).

The goals of education in the pretransplant period are to teach patients about their underlying lung disease, the transplant procedure itself, and expectations following transplantation. Patients can also be taught techniques for self-care and self-assessment that will be useful before and after surgery. The psychosocial stresses of waiting for transplantation are considerable. Many patients feel as though their lives are "on hold." Some may have moved away from family and social support networks to live close to the transplant center. Providing support for patients and families during this time, whether through formal group support sessions or informal contact with supportive staff and other patients, helps patients cope better with these problems.

Posttransplant Rehabilitation

After lung transplantation, patients must learn to cope with a new level of function, new expectations, and a new set of problems. Rehabilitation for patients in this phase can facilitate physical reconditioning, help implement self-care and assessment techniques, and facilitate coping with the psychosocial adaptations to a new lifestyle.

Goals of exercise training after rehabilitation are improved physical work tolerance and continued assessment of symptoms and oxygenation as early warning signs of complications, including rejection and infection. Educational goals are focused on self-care and assessment and the importance of compliance with a new medical regimen. Psychosocial support can assist with adaptation to a new set of stresses related to additional demands and expectations from both patients for themselves and significant others. Patients who are used to being sick, disabled, and cared for by others may now be expected to be well, function independently, return to work, and provide support for others.

Lung Volume Reduction Surgery

Among patients with severe emphysema, pulmonary rehabilitation is commonly part of the management plan to optimize them prior to lung volume reduction, either surgically or bronchoscopically, and to facilitate recovery following surgery.[15,16] Since these patients have severe, disabling chronic lung disease, they are typically good candidates for pulmonary rehabilitation. Enrolling patients in rehabilitation prior to surgery has the advantage of optimizing their functional status, improving physical and psychological symptoms, helping them learn more about their disease and alternative treatment options, and improving their skills for coping and actively co-managing their disease. Patients can then make an informed decision about surgical treatment based upon their optimal level of baseline function. After surgery, similar to the posttransplant period, rehabilitation helps patients to adapt to new levels of function and to reassess symptoms and oxygenation needs.

Rehabilitation After Lung Resection

Patients who undergo pulmonary resection frequently experience a significant increase in symptoms and reduced functional status. This is particularly true for patients with underlying chronic lung disease. Most commonly, surgery is used to treat patients with thoracic neoplasms who are deemed to have resectable disease and are operative candidates. Following resection, these patients with already limited lung function have to learn to adapt to a new, lower level of function. Similar changes may be observed in patients who undergo radiation therapy. Patients in a stable phase of their treatment or in remission may be appropriate candidates for pulmonary rehabilitation. Improvement in health status, physical and psychological symptoms, exercise tolerance, and quality of life—as well as reduced healthcare burdens—are potential benefits. These patients' survival may be as limited by their underlying lung disease as by their treated malignancy.[8–13]

EXPANDING ACCESS

Despite compelling evidence of benefits, pulmonary rehabilitation is delivered to <5% of eligible patients.[46,53,54] Limited program availability and geographic disparity among existing programs are significant barriers to broad and equitable delivery of pulmonary rehabilitation.[55] In addition, insufficient clinician and patient knowledge, patient fear of exercise and rehabilitation, and transportation and social barriers are factors that hinder the uptake of pulmonary rehabilitation.[54] During the 2020 global COVID-19 pandemic, center-based pulmonary rehabilitation programs were generally unavailable to these high-risk patients due to social distancing recommendations. Alternative models that enable delivery of pulmonary rehabilitation in the home setting may be important in making this important treatment available to more patients.[56] The use of telehealth technology to move pulmonary rehabilitation programs away from centers and into patients' homes shows promise.[57] For example, a randomized controlled trial of 166 patients with COPD assigned to receive 8 weeks of outpatient pulmonary rehabilitation demonstrated noninferiority for the home-based compared with center-based strategy on the 6-minute walk distance.[58] Such programs can be remotely delivered using videoconferencing, web-based platforms, mobile phones, and/or telephone with simple and portable exercise equipment.[59] In addition, these programs may also need to incorporate technology-enabled assessments to individualize exercise therapy, monitor safety, and evaluate effectiveness. While home-based strategies are associated with higher patient adherence,[60] limited in-person and group contacts may minimize some of the psychosocial benefits that are important features of center-based programs. Nevertheless, telerehabilitation may be necessary in some circumstances.

SUMMARY AND FUTURE OF PULMONARY REHABILITATION

Pulmonary rehabilitation has been well established as a means of improving functional status and reducing the disability and economic burden of the growing number of patients with chronic lung diseases. In adopting a broad rehabilitation medicine perspective, such programs provide interdisciplinary expertise directed toward the needs of the individual disabled patient.

Much of the experience in pulmonary rehabilitation has been in patients with COPD. However, it is clear that similar benefits can result for patients with other disabling chronic pulmonary conditions as well as those recovering from acute processes. Pulmonary rehabilitation may also play an important role in the preoperative evaluation, preparation, and postoperative recovery of patients undergoing surgical procedures, including lung transplantation, lung volume reduction surgery, and lung resection. In many parts of the world, a major challenge for the widespread application of pulmonary rehabilitation to the large number of patients with chronic lung diseases relates to acceptance by health policy makers and health insurers about the benefits and cost savings associated with this treatment. Given the small number of patients who currently have access to pulmonary rehabilitation programs and services, expanding access to the large number of other patients who could benefit is of particular importance. The use of new technologies, such as telemedicine, to reach more patients is particularly appealing, especially following the COVID-19 pandemic that seriously restricted access to the usual outpatient pulmonary rehabilitation centers. It is hoped that, with time and experience, the benefits of pulmonary rehabilitation as an effective, preventive health intervention that can improve patient outcomes and reduce healthcare costs will be better recognized and more widely applied.

CHAPTER 43

The Biology of Asthma

Geoffrey L. Chupp
Matthew C. Bell
William W. Busse

INTRODUCTION

Asthma is a chronic inflammatory disease of the airways characterized by persistent variable symptoms that include shortness of breath, cough, and wheezing.[1] It is the most common chronic lung disease and one of the most prevalent diseases in the United States, affecting more than 20 million adults and 7 million children.[2] Attempts to elucidate the cellular and molecular effector pathways that contribute to asthma have led to the realization that it is a protean disease driven by many cell types and mechanisms. This degree of mechanistic variation explains the numerous clinical phenotypes that are now recognized, as well as differences in response to treatment with inhaled therapies and the targeted biologic treatments that have entered the clinic over the last decade.

Core to the pathogenesis of asthma is bronchoconstriction and variable airflow obstruction, airway hyperresponsiveness, and chronic airway inflammation.[3] It is, however, the complex interplay between these factors that eventually defines the clinical expression of disease in individual patients. Here, a close examination of the cellular and molecular mediators involved in each of these components will be presented to allow for a more comprehensive understanding of this complex disease.

ADAPTIVE AND INNATE INFLAMMATORY RESPONSES IN ASTHMA

The inflammatory response in the airways of patients with asthma is complex, heterogenous, and evolves over time, but the prototypical events seen in most patients with asthma (65%–80%) are type 2 (T2) inflammatory responses (Fig. 43-1). T2 inflammation is currently thought of as being driven by both innate and adaptive mechanisms to varying degrees in each individual with asthma, which explains much of the heterogeneity in clinical presentation, biomarkers, and treatment response. The most well-understood T2 pathway is the

Figure 43-1 Inflammatory pathways in asthma. The T2 inflammatory pathway with contributions from the adaptive and innate immune response leads to production of T2 cytokines IL-4, IL-5, and IL-13. The non-T2 pathway with activation of T_H1 and T_H17 cells leads to neutrophil activation. Both inflammatory pathways can lead to asthma symptoms and airway remodeling. TSLP is the target of tezepelumab; IL-5 is the target of reslizumab and mepolizumab; IgE is the target of omalizumab; CRTH2/PGD2 is the target of fevipiprant; IL-4Rα is the target of dupilumab; IL5R is the target of benralizumab. allergic inflammatory response that is, largely, an adaptive immune response to initial and subsequent exposures to inhaled allergens. While the key cellular and molecular mediators will be described in greater detail later in the chapter, we now describe the evolution of the allergic response. This is the foundation upon which other concepts have been constructed and illustrates the basis for chronic variable changes that occur in the airway in asthma and in the clinical expression of disease.

The adaptive response begins when a novel antigen (allergen) enters the airway of an individual at risk, where it becomes trapped in the mucus layer lining the airway. Here it is endocytosed by professional antigen-presenting dendritic cells. During this process it encounters tentacle-like projections or "dendrites" of the dendritic cells that are intercalated amongst bronchial epithelial cells throughout the airways.[4,5] After the uptake and processing of the antigen, the dendritic cells migrate to local lymph nodes in the lung and mediastinum, where the antigen is presented to naïve $CD4^+$ T cells via the T cell receptor (TCR).[5] Additional signals derived from the dendritic cell determine which type of $CD4^+$ memory T cell the naïve T cell will become (i.e., Th1, Th2, Th17, Treg)—which determines what repertoire of cytokines the memory T cell will produce. Prior to this event, the dendritic cell is influenced by a complex network of molecular signals that are derived from airway epithelial cells and other local cell types. For example, the production of epithelial cytokines or alarmins—such as thymic stromal lymphopoietin (TSLP), interleukins (IL)-33 and -25, and granulocyte-monocyte colony-stimulating factor (GM-CSF)—creates a milieu for dendritic cells to promote naïve $CD4^+$ T cell polarization into T_H2 that creates an environment favorable for the persistence of allergic inflammation.[5] Other cell types also are activated including B cells, which, in the presence of IL-4 and IL-13, are influenced to produce antigen-specific IgE that binds to high-affinity IgE receptors ($Fc\varepsilon RI$) on mast cells and basophils. Upon rechallenge with the sensitizing antigen, the sensitized T_H2-differentiated $CD4^+$ T cells are recruited back to the airway by other signals, such as chemokines CCL17 and CCL22 secreted by dendritic cells.[6] Upon arrival to the airway, the $CD4^+$ T_H2 cells become key sources of the T_H2 cytokines IL-4, IL-5, and IL-13, which serve as the molecular catalysts that drive the T_H2 inflammatory response.[6]

Upon subsequent exposure to the antigen, the local environment of the airways is now primed to respond to the antigen in the future, rich with T_H2 cytokines and antigen-specific IgE, which act on other cell types, either present or recruited to the airway, to amplify the allergic inflammatory response. When inhaled antigen cross-links membrane-bound IgE on mast cells and basophils, a variety of preformed and synthesized meditators are released and cause bronchoconstriction, airway wall edema, and local tissue damage.[7] Mast cells release chemoattractants such as leukotrienes and chemokines that recruit additional inflammatory cells including eosinophils, basophils, neutrophils, and lymphocytes to establish a late-phase inflammatory response.[7] The eosinophil appears to be, in most cases, the most important and abundant inflammatory cell associated with the late-phase response and the primary cell contributing to inflammation, tissue damage, and airflow obstruction through a vast number of mediators that are reviewed below.[8] Eosinophil products can cause local tissue damage, mucus hypersecretion, increased vascular permeability, and smooth muscle contraction, and they sustain the inflammatory response by recruiting other cell types that perpetuate the inflammation.[7,8] The roles of macrophages, neutrophils, and basophils in the pathogenesis of the acute- and late-phase allergic inflammatory responses are less well defined but are likely important in other subtypes of disease and clinical settings as outlined below.

While the acute allergic response to allergen illustrates the pattern of inflammation seen in asthma, it should be noted that other forms of inflammation also play important roles in asthma pathogenesis. Viral respiratory infections, especially with human rhinovirus (HRV), are important triggers of asthma exacerbations.[9] The response to HRV is a primarily T_H1-driven response with increased production of IL-8 and IL-1β and the initial appearance of airway neutrophilia, in contrast to the T_H2 response seen after allergen exposure.[9,10] With HRV infections, there is also release of epithelial cell alarmins, with IL-33 in particular activating ILC2 to generate IL-5 and recruit eosinophils to the airway and cause inflammation and airflow obstruction.[11] In asthma, there is evidence that in the milieu of the T2 response there is diminished production of type I and III interferons. Some patients with asthma may be deficient in these critical antiviral cytokines, which leads to increased risk for viral respiratory infections and a greater susceptibility to exacerbations of asthma.[9,10]

The pattern of the acute- and late-phase inflammatory responses to antigen is a central paradigm of asthma that leads to chronic variable symptoms and chronic inflammation associated with the disease. Many of the cell types and inflammatory mediators seen in asthma that were briefly touched upon in the preceding paragraphs will now be discussed in more detail.

CELL TYPES IN ASTHMA

A review of the pathogenesis of any complex disease begins at the cellular level. The importance of cells of the immune system, including mast cells, basophils, $CD4^+$ T cells, eosinophils, neutrophils, macrophages, dendritic cells, and T lymphocytes, as well as their molecular mediators, has long been recognized and appreciated in the development and regulation of inflammation. The contribution of airway smooth muscle cells, especially in relationship to the acute asthmatic response, also has been well documented. More recently, innate immune responses have been increasingly recognized as important drivers of T2 inflammation independent of the adaptive immune response in as many as 50% of patients with severe asthma.[12] In addition, bronchial epithelial cells of the airway have become the focus of intense research and are emerging as critical to both the acute and chronic inflammatory responses in asthma. Their role in airway inflammation and airway remodeling is increasingly cited as a major contributor to the severity of this disease.

■ Cells of the Immune System in Asthma

Below we consider a variety of cellular components of the immune system in asthma.

■ Mast Cells

Human mast cells are derived from the same $CD34^{+/}cKit^+$ hematopoietic stem cell population that also gives rises to eosinophils, basophils, neutrophils, and monocytes.[13] They are resident cells in most tissues of the body and are commonly found in association with blood vessels, nerves, and surfaces that have contact with the external environment.[14] Mast cells (MC) exist in two types in humans and are differentiated by their immunohistochemical staining properties.[15] MC_T mast cells contain only the neutral protease tryptase, while MC_{TC} mast cells contain chymase, carboxypeptidase A3, and cathepsin G–like protease in addition to tryptase.[15–17] In normal lung tissue, mast cells are located in the subepithelium of the bronchi, bronchioles, and alveolar walls and are almost exclusively of the MC_T type.[15] This distribution of mast cell types is also seen in mild asthma. However, in severe asthma, mast cells are primarily of the MC_{TC} type and are decreased in number in the submucosa but are increased in the airway epithelium, a finding not seen in normal airways or milder disease.[18] Mast cells also infiltrate airway smooth muscle bundles in asthma, where they likely contribute to inflammation, airway hyperresponsiveness, and bronchoconstriction through the action of their released mediators.[19]

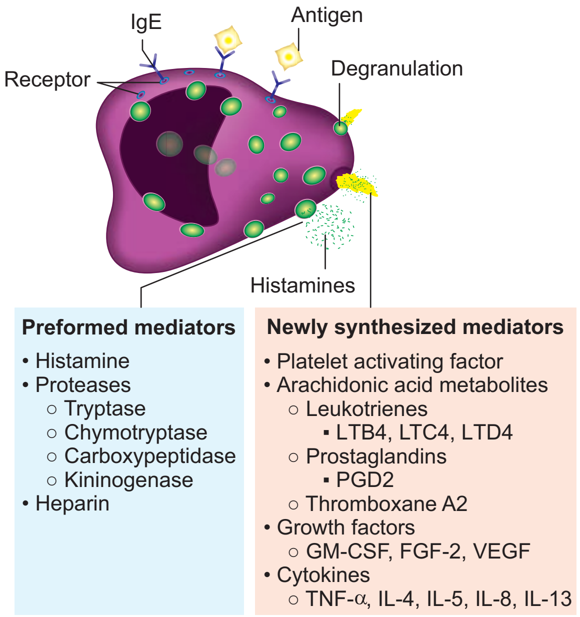

Figure 43-2 The mast cell and its mediators. FGF-2, fibroblast growth factor 2; GM-CSF, granulocyte-monocyte colony-stimulating factor; TNF-α, tumor necrosis factor alpha; VEGF, vascular endothelial growth factor.

While the role of mast cells in allergic (IgE-mediated) asthma is well established, these effector cells also appear to be important in nonallergic disease.[20] In allergic responses, antigen-specific IgE molecules bind allergen and cross-link high-affinity IgE receptors (FcεRI) present on the mast cell surface. Mast cells can also be activated by nonallergic stimuli such as heat and bronchospasm. This results in the release of preformed mediators, such as histamine, tryptase, chymase, and heparin, as well as tumor necrosis factor alpha (TNF-α) and vascular endothelial growth factor (VEGF).[21] Upon activation, mast cells generate and release newly synthesized mediators, which contribute to the ongoing inflammatory milieu. These include leukotrienes (predominantly LTC4); prostaglandins (predominantly PGD_2); thromboxane A2; platelet activating factor (PAF); growth factors including GM-CSF, fibroblast growth factor 2, and VEGF; and many other cytokines including but not limited to TNF-α, IL-4, IL-5, IL-8, and IL-13 (Fig. 43-2).[21,22]

The effect of mediators released from mast cells contributes to numerous features of the asthmatic response.[7] Histamine, leukotrienes, and proteases contribute to increased mucus production. Prostaglandins, leukotrienes, thromboxane A2, and histamine cause bronchoconstriction and increase vascular permeability. These proteases produce tissue damage and activation of many protein precursors. This, in turn, contributes to the recruitment, differentiation, and activation of other inflammatory cells, which results in the propagation of the inflammatory response.

■ Basophils

With the exception that basophils are present primarily in the peripheral circulation, basophils share many similarities with mast cells. These enigmatic cells share a common progenitor cell with mast cells, also express FcεRI on their cell surface, and release both preformed and newly synthesized mediators and cytokines upon cross-linking by IgE-antigen complexes on their surface. Like mast cells, the major preformed mediator released from basophils is histamine. Preformed heparin and tryptase also are released, albeit at lower concentrations than by mast cells.[23] Basophils synthetize and release LTC_4 upon activation, but unlike mast cells, they do not produce PGD_2.[23] Upon activation, basophils produce large quantities of IL-4 and IL-13.[23] Basophils have been shown to contribute to T_H2 differentiation by presenting antigen via major histocompatibility complex (MHC) class II and co-stimulatory molecules,[24] and basophils, along with eosinophils, are a primary target of the alarmin IL-33, a potent promoter of allergic inflammation and T_H2 polarization.[25]

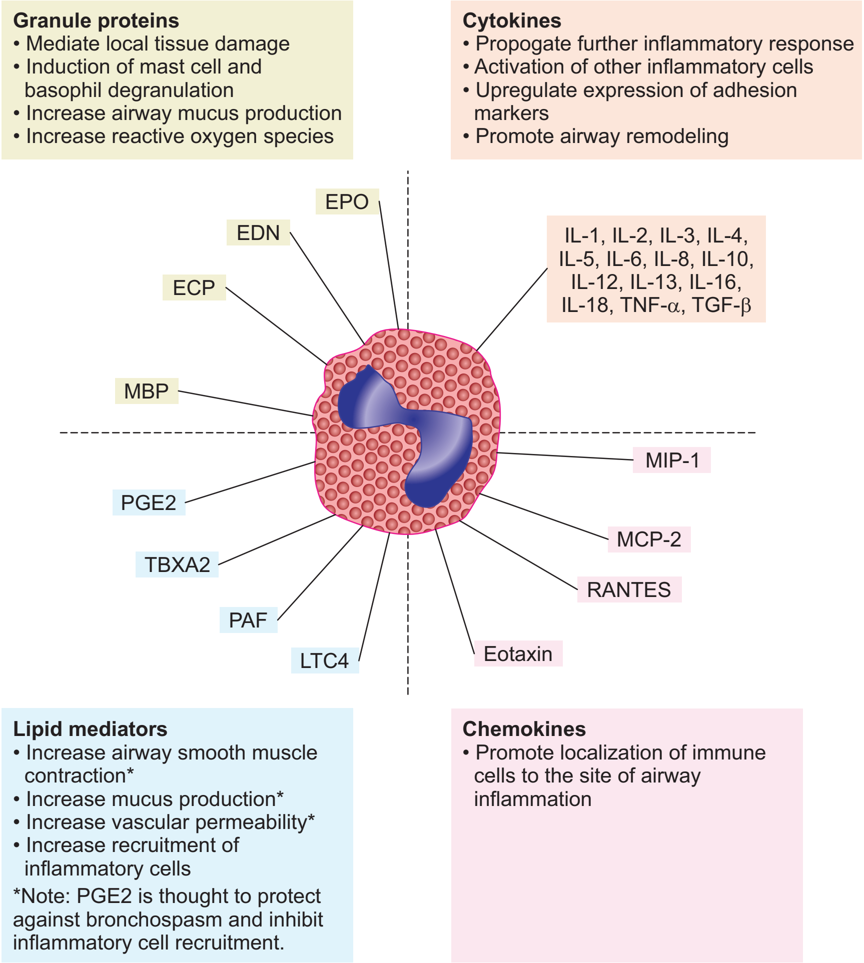
■ Eosinophils

Eosinophils, like basophils and mast cells, are granulocytes derived from $CD34^+$ hematopoietic stem cells. Early eosinophil production is highly dependent upon the presence of GM-CSF and IL-3.[26] Eosinophil precursors are recruited to the airway in asthma as the result of cytokine and chemokine signaling. This signaling involves IL-5; eotaxins; CCL5/regulated on activation, normal T cell expressed and secreted (RANTES); macrophage inflammatory protein (MIP) 1α; and macrophage chemotactic factors 2, 3, and 4 (MCP-2, -3, and -4).[27] IL-5 is critically important to the terminal differentiation of eosinophils and release from the bone marrow.[26] Blockade of the IL-5 pathway with biologic therapies in patients with asthma results in the near elimination of eosinophils from the blood, highlighting this cytokine's importance to this cell's association and contribution to asthma.[28]

Once in the airway, eosinophils are activated by mechanisms not clearly established to contribute to the inflammatory response by releasing a wide variety of mediators. These include cytokines (IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-13, IL-16, IL-18, tumor necrosis factor α [TNF-α], and transforming growth factor α and β [TGF-α and TGF-β]), chemokines (MIP-1, MCP-2, RANTES, and eotaxin), and lipid mediators (PGE_1, PGE_2, thromboxane B_2, PAF, and LTC_4) (Fig. 43-3).[29,30] Eosinophils secrete granule proteins, which are recognized as the eosinophil's essential mechanism in defense against parasites.[29,31] Eosinophils contain both primary and secondary granules. The primary granules contain Charcot-Leyden crystal protein, while the secondary granules contain the four principal cationic proteins: MBP (major basic protein), ECP (eosinophil cationic protein), EDN (eosinophil-derived neurotoxin), and EPO (eosinophil peroxidase).[29] These cationic proteins contribute to the pathogenesis of asthma through the induction of mast cell and basophil degranulation (ECP and MBP), increasing airway mucus production (ECP), and formation of reactive oxygen species (EPO).[29] The presence of Charcot-Leyden crystals has proved to be a key factor in the eosinophil's contribution to airway inflammation.[32]

Over the past 30 years, the role of the eosinophil in asthma has undergone considerable re-evaluation. Since the discovery of the eosinophil by Ehrlich in 1879 and the later discovery that Ehrlich's cells were present in the sputum of asthmatic patients, the eosinophil has been viewed as the primary effector cell in asthma.[33] Studies have noted that peripheral blood eosinophilia is a characteristic of asthma, correlated with disease severity, and that eosinophilic infiltrates were in the airways of asthma patients at autopsy, regardless of whether asthma was the primary cause of death.[34,35] Later studies detected increased eosinophils and eosinophil products in bronchoalveolar lavage (BAL) fluid after antigen challenge.[36] This concept of the eosinophil as a principal effector in asthma was largely unvalidated until the new millennium, when monoclonal antibodies against IL-5 (mepolizumab and reslizumab) and the IL-5 receptor (benralizumab) were demonstrated to be potent modulators of eosinophil levels in the blood, asthma exacerbations, and airway obstruction.[28]

Initial studies with monoclonal antibodies against IL-5 in patients with asthma (independent of their level of eosinophilic inflammation) showed a decrease in sputum and peripheral blood eosinophilia, as expected, but failed to demonstrate significant benefit in a wide variety of clinical outcome measures, including symptom score or improved airflow obstruction.[37,38] Although the



Granule proteins
- Mediate local tissue damage
- Induction of mast cell and basophil degranulation
- Increase airway mucus production
- Increase reactive oxygen species

Cytokines
- Propogate further inflammatory response
- Activation of other inflammatory cells
- Upregulate expression of adhesion markers
- Promote airway remodeling

Lipid mediators
- Increase airway smooth muscle contraction*
- Increase mucus production*
- Increase vascular permeability*
- Increase recruitment of inflammatory cells

*Note: PGE2 is thought to protect against bronchospasm and inhibit inflammatory cell recruitment.

Chemokines
- Promote localization of immune cells to the site of airway inflammation

lack of effect on these parameters of clinical asthma was a surprise, it contributed to the current understanding of asthma as a highly heterogeneous disease where inflammatory cells like eosinophils can play variable roles in different patients, thus emphasizing the importance of determining the individual phenotype of an asthma patient when judging the likely efficacy of a particular biologic agent.[28] Studies with the anti-IL-5 monoclonal antibodies mepolizumab and reslizumab, and the anti-IL-5 receptor antibody benralizumab, were conducted in patients with uncontrolled asthma. Treatment of patients with a history of multiple exacerbations and persistent eosinophilia in the blood or sputum or high exhaled nitric oxide levels despite treatment with inhaled corticosteroids (ICS) led to a substantial reduction in systemic corticosteroid-requiring exacerbations.[39,40] From these studies emerged the concept that there exists a subtype of patient with asthma in which the eosinophil plays a key role. Eosinophils are also a prime contributor to airway remodeling, mucus hypersecretion, and formation of mucus plugs, discussed later in the chapter.[41]

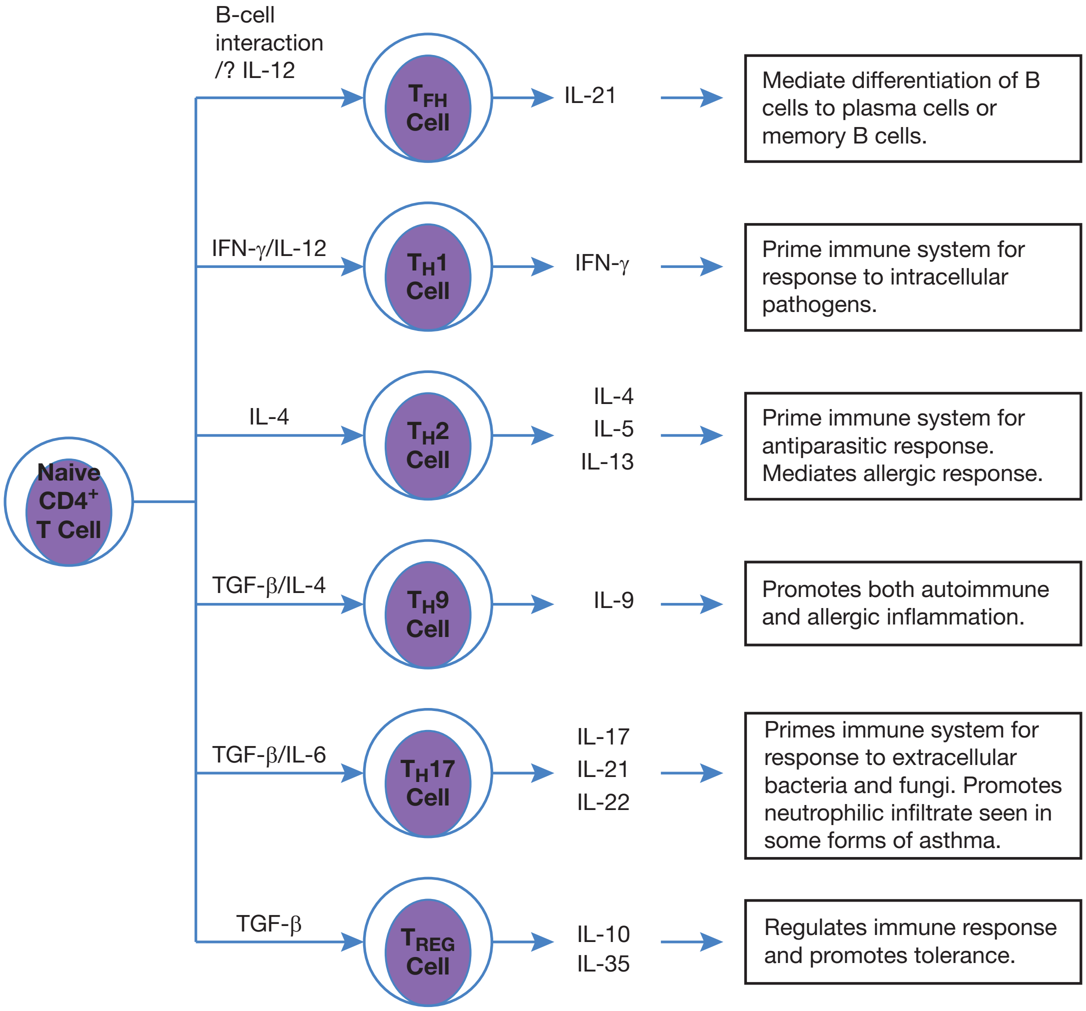
■ Neutrophils

Neutrophils are granulocytes also derived from CD34$^+$ hematopoietic stem cells that are normally present in the bloodstream, as well as in various tissues, including the lung. They contain primary (azurophilic) and secondary (specific) granules, which contain antimicrobial enzymes, neutral proteases, and acid hydrolases.[42] Neutrophils are attracted to the airway by numerous cytokines and chemokines including IL-8, IL-17, and granulocyte colony–stimulating factor (G-CSF).[43,44] Airway neutrophilia can be seen in many respiratory conditions, viral respiratory infections, COPD, and asthma.[10,44]

The role of neutrophils in the initial response to a viral respiratory infection is well understood. In response to inoculation with a respiratory virus, such as HRV, dendritic cells and other mononuclear cells produce proinflammatory cytokines and chemokines, which recruit neutrophils to the airway.[10] Neutrophils contribute to the inflammatory milieu by secreting cytokines such as TNF-α, IL-1, IL-8, and IL-18, to attract other inflammatory cells, upregulate cytokine production, produce airway inflammation, and enhance bronchial hyperresponsiveness.[45] Neutrophil products, such as elastase, have direct effects on the airway and contribute to mucus production.[10] Furthermore, HRV activation of neutrophils releases DNA-containing NETs that, in turn, activate $\mathrm{T_H}$2 lymphocytes to release T2 cytokines.[46] In addition, because neutrophils are found in some patients with severe asthma, they have been hypothesized to play a prominent role in this phenotype.[47] Neutrophilic inflammation has been noted in the sputum of patients with severe asthma exacerbations, in BAL fluid from patients with noninfectious status asthmaticus, and in autopsy specimens from the airway in patients with acute, fatal asthma.[48–50] Other studies have demonstrated subgroups of patients with chronic asthma in whom the primary inflammatory cell type in the sputum is neutrophils rather than eosinophils.[51,52] These patients are more often female, obese, difficult to treat, and less responsive to treatment with corticosteroids.[32]

■ Lymphocytes

Cells of lymphoid lineage are also key mediators of innate and adaptive immune responses in asthma. Among them, T lymphocytes, derived from the common lymphoid progenitor, are a household name in asthma. Numerous subsets of T cells have been identified



B-cell interaction /? IL-12
T_{FH} Cell
IL-21
Mediate differentiation of B cells to plasma cells or memory B cells.
IFN-γ/IL-12
T_H1 Cell
IFN-γ
Prime immune system for response to intracellular pathogens.
IL-4
T_H2 Cell
IL-4
IL-5
IL-13
Prime immune system for antiparasitic response. Mediates allergic response.
Naive $CD4^+$ T Cell
TGF-β/IL-4
T_H9 Cell
IL-9
Promotes both autoimmune and allergic inflammation.
TGF-β/IL-6
T_H17 Cell
IL-17
IL-21
IL-22
Primes immune system for response to extracellular bacteria and fungi. Promotes neutrophilic infiltrate seen in some forms of asthma.
TGF-β
T_{REG} Cell
IL-10
IL-35
Regulates immune response and promotes tolerance.

Figure 43-4 $CD4^+$ T lymphocyte subsets. IFN-γ, interferon gamma; TGF-β, transforming growth factor beta.

and are important contributors to asthma, including $CD4^+$ helper T cells and their subsets (T_H1, T_H2, T_H9, and T_H17), $CD8^+$ cytotoxic T cells, and regulatory T cells (T_{Reg}).

$CD4^+$ helper T cells recognize antigens presented to them by antigen-presenting cells (APCs) and, in turn, secrete cytokines to influence the adaptive inflammatory response. In the airway, the dendritic cell is the most important APC (discussed in detail below). A complex series of events involving cytokines and various transcription factors determines whether $CD4^+$ T cells will differentiate into T_H1, T_H2, T_H9, or T_H17 cells (Fig. 43-4).[53]

As outlined above, T_H2 cells are recognized as the primary drivers of inflammation in allergic asthma and other allergic diseases. When T_H2 cells encounter antigen presented by dendritic cells, they produce IL-4, IL-5, and IL-13, all of which play critical roles in the pathogenesis of asthma and pathophysiology in the clinical disease. This has been demonstrated by the detection of increased levels of these cytokines in the BAL fluid of patients with asthma.[54,55] IL-4 increases IgE production by plasma cells, IL-5 is critical to the terminal differentiation and homing of eosinophils to the airway, and IL-13 increases IgE production and drives airway hyperresponsiveness and tissue remodeling.[56]

The role of T_H1 cells in asthma is not as well defined as that of T_H2 cells. Although it has been presumed that T_H1 cells counteract the asthma-inducing effects of T_H2 cells, this is likely an oversimplification as T_H1-associated cytokines have been shown to be increased during asthma exacerbations.[57] Some studies have also suggested that T_H1 cells may play a more prominent role in severe asthma since levels of the canonical T_H1 cytokine, interferon γ (IFN-γ), are increased in the BAL fluid of patients with severe asthma.[58]

T_H9 cells are another adaptive cell type whose primary cytokine is IL-9. T_H9 cells function similarly to T_H2 cells in that they allow persistence of and amplify allergic inflammatory responses. Mast cells are the primary IL-9 receptor–bearing cell, and T_H9 cells are important contributors to the mast cell activation that is notable in asthma.[22] Because mast cells also produce VEGF and fibroblast growth factor (FGF)-2, T_H9 cells likely contribute to airway remodeling as well.[22] The role of targeted therapeutics against the IL-9 pathway in the treatment of asthma remains to be determined.

The last several decades of asthma research and therapeutic development have focused on T2 inflammation, bringing multiple anti-T2 therapeutics to the clinic. As a result, clinicians now have many options to treat allergic and eosinophilic asthma. In contrast, our understanding of non-T2 inflammation in asthma has been hampered by a lack of robust animal models and a consensus on the definition of low-T2 disease. In this regard, the role of T_H17 cells in asthma is an emerging area of intense research. With the identification of a subtype of asthma with primarily neutrophilic inflammation, the role of IL-17 (the primary cytokine produced by T_H17 cells) in asthma has become of an area of considerable interest. Although IL-17 is increased in patients with severe asthma,[59] it is also found in high concentrations in patients with mild asthma (forced expiratory volume in 1 s [FEV_1] >70% predicted) and correlates negatively with the provocative concentration that causes a 20% reduction in FEV_1 (PC_{20}).[60] Thus, while T_H17 cells most certainly play a role in patients with primarily neutrophilic asthma, they are also important in other forms of disease. Furthermore, treatment of severe asthma with anti-IL-17 monoclonal antibodies has not shown a consistent effect. At present, there are no biomarkers to identify the IL-17/T_H17 phenotype of asthma.[61]

The primary function of $CD8^+$ cytotoxic T cells is the destruction of human cells that are infected with viruses or other intracellular pathogens. $CD8^+$ T cells are also likely to play a role in asthma, although the extent of their contribution has yet to be fully elucidated.[56] IL-4- and IL-5-producing $CD8^+$ T cells are present in the airways of asthmatic patients.[62] IL-5 production by $CD8^+$ T cells is increased in the presence of a viral respiratory infection, and the overall cytokine production by $CD8^+$ T cells correlates with asthma severity.[63,64] Whether $CD8^+$ T cells function as direct contributors or bystanders in the worsening of asthma has yet to be determined.[56]

T_{Reg} cells also appear to play a critical role in asthma development. T_{Reg} cells serve to limit inflammatory responses and promote immune tolerance through the production of IL-10 and TGF-β.[56,65] In patients with asthma and other allergic disorders, T_{Reg} cells appear to be less effective at limiting T_H2 inflammation.[66,67] However, after allergen immunotherapy, for example, T_{Reg} cells increase in the nasal mucosa and may act to promote allergen tolerance.[68] Interestingly, farm exposure early in life is associated with a decreased incidence of allergic disease and asthma, a fact that may be related to increased numbers and function of T_{Reg} cells in infants living in this environment.[69]

Natural killer cells (NK cells) are members of the innate immune system that serve as a first line of defense against infections. Their role in the pathogenesis of asthma has yet to be fully elucidated. They proliferate in response to viral respiratory infections, and their numbers increase during asthma exacerbations.[70] NK cells are capable of producing numerous cytokines including IFN-γ, IL-4, IL-5, and IL-13.[71] NK cells from patients with atopic asthma are skewed toward the production of IL-4 as opposed to IFN-γ upon activation.[71] IFN-γ production by NK cells is also inhibited by prostaglandin D2, a T_H2-promoting lipid mediator produced by mast cells.[72] NK cells may also play a role in "dendritic cell editing" by killing immature dendritic cells, which might influence the development of the type of T_H response.[73]

Macrophages and Dendritic Cells

Macrophages and dendritic cells are descendants of the $CD34^+$ hematopoietic stem cell and arise from a common committed precursor cell.[74] Macrophages arise from circulating monocytes and function primarily to clear debris and microbes from the airway. They may also function as antigen-presenting cells, although this role is likely less important than that of the dendritic cell.[75] Alveolar macrophages may further differentiate into M1 or M2 subsets based on exposure to various cytokines and Toll-like receptor (TLR) agonists.[74] M1 macrophages are "classic" macrophages that clear microbes from the airway. They also produce cytokines, such as IL-12, IL-6, and TNF-α, as well as high levels of nitric oxide (NO).[74] M1 macrophages have traditionally been described as suppressing allergic inflammation, primarily through their secretion of T_H1 cytokines such as IL-12.[74]

Differentiation of monocytes into M2 macrophages is influenced by an environment rich in T_H2 cytokines such as IL-4 and IL-13, indicating they have a role in asthma. When compared with M1 macrophages, M2 macrophages are less effective at clearing intracellular pathogens.[74] They release cytokines such as IL-13 and thus are likely to contribute to the airway hyperresponsiveness in T2 inflammation.[74]

Dendritic cells are the lung's primary presenter of antigen to T cells and are intimately arranged among bronchial epithelial cells in the airway wall. This positions the dendritic cell at a critical junction in determining what type of adaptive T cell response will be directed by the antigen presented by the dendritic cell (e.g., T_H1, T_H2). Dendritic cells in humans exist in two broad categories: the myeloid dendritic cell (mDC) and the plasmacytoid dendritic cell (pDC). While both types of dendritic cells are present in the human lung, their relative localization within the lung is poorly understood.[5] Upon encountering antigen in the airway, dendritic cells migrate to local lymph nodes where they present antigen to T lymphocytes. Both pDC and mDC levels increase in the airway (and coincidently decrease in the blood) after exposure to inhaled allergen.[76–78] Because dendritic cells lie close to the epithelial barrier, they receive numerous signals from epithelial cells, which can influence their effect on T cells. Thymic stromal lymphopoietin (TSLP), the canonical alarmin and target of the monoclonal antibody tezepelumab, is produced by epithelial cells. This product promotes dendritic cells to drive T_H2 differentiation and recruit T_H2 cells to the airway.[5] Other epithelial cell–derived factors, such as GM-CSF, TNF-α, CCL-20, IL-1β, and TNF-related apoptosis-inducing ligand (TRAIL), have similar T_H2-promoting effects.[5] pDCs represent the lung's primary source of IFN-α, a potent antiviral cytokine. These cells are recruited to the lung during viral infections.[79] As viral infections commonly precede asthma exacerbations and may predispose infants to develop asthma, this role of the pDC should be emphasized.[80] The importance of pDC to the development of asthma was illustrated by a recent study which showed that levels of pDC in childhood were inversely correlated with number and severity of viral respiratory infections, increased episodes of wheeze, and increased asthma diagnosis.[81] The function of mDC is not as well known in human asthma, but the role of both cell types in contributing to the development and propagation of the disease will continue to be an important area of asthma research.

Structural Cells of the Airway

Other cellular components of the asthmatic response to be considered include structural cells of the airway: smooth muscle and airway epithelial cells.

Airway Smooth Muscle

Given that bronchospasm and bronchial constriction are central components of asthma, it is intuitive that the cell type responsible for this component, the airway smooth muscle cell, would be a key factor in asthma pathogenesis and pathophysiology. While this cell's importance seems obvious, the details of how airway smooth muscle function differs in the asthmatic airway compared with the normal airway have been elusive. It has been well documented that the smooth muscle layer surrounding the airway is thicker in asthmatics compared to nonasthmatic controls, likely due to remodeling via both smooth muscle hypertrophy and hyperplasia.[82] Increased inflammatory and mast cells can be found within the smooth muscle bundles of asthmatic airways, an indication of the increased communication between these cells, the airway epithelium, and the smooth muscle in asthma.[19] Numerous cytokines, chemokines, and growth factors are involved in these interactions, including those produced by the airway smooth muscle cells and by other cell types with which the airway smooth muscle cell communicates. Airway smooth muscle cells are more prolific producers of these cytokines and proliferate more rapidly in asthma compared with normal smooth muscles.[83]

Early efforts to treat asthma focused on preventing or reversing contraction of bronchial smooth muscles. β-2 agonists, both short- and long-acting, have long been key components in the treatment of asthma, by directly acting on airway smooth muscle to produce bronchodilation. More recently, attempts to alter function of airway smooth muscle with the use of bronchial thermoplasty have shown improvement in asthma control, further supporting the role that airway smooth muscle plays in asthma pathophysiology.[84,85]

■ Airway Epithelial Cells

The bronchial epithelium lining the airway is an area of intense research, and its importance, beyond being a simple anatomic barrier, is being increasingly recognized and appreciated. The airway epithelium has a vast surface area (100 m^2) that is in contact with some 10,000 L of inhaled air daily.[86] As the area of initial contact between the body and the external airborne environment, functions of the airway epithelium are a key determinant of the body's response to airborne substances.

The airway epithelium is composed of three major cell types: ciliated columnar epithelial cells, mucus-secreting goblet cells, and surfactant-secreting Clara cells.[86] Both overproduction of mucus by goblet cells and underproduction of important anti-inflammatory peptides by Clara cells have been noted in patients with asthma.[87,88] The tight junctions between epithelial cells have also been noted to be defective in patients with asthma, which decreases the ability of the airway epithelium to act as a protective barrier.[86] The airway epithelium in asthma is also less capable of defending itself against reactive oxygen species, a defect that leads to damage when the airway is inflamed.[89] Epithelial cells in asthma produce lower amounts of type I interferon in response to respiratory viruses, which can increase the risk and severity of respiratory infections and promote asthma exacerbations.[90] More recently, the importance of epithelial-derived alarmins, including IL-25 and -33, which promote both T1 and T2 inflammatory responses, has been demonstrated in asthma linking the airway epithelium with the inflammation evident in both T2-high and non-T2 inflammation.[91,92] This realization has led to the development of monoclonal antibodies directed against TSLP (tezepelumab) and IL-33 (itepekimab). In a genome-wide association study, Shrine et al. found an association between polymorphisms in MUC5AC and moderate to severe asthma raising the possibility that this gene contributes to the development of more severe asthma.[93]

MOLECULAR MEDIATORS IN ASTHMA

The aforementioned cells are able to initiate, perpetuate, coordinate, and regulate the inflammatory process with the synthesis and secretion of several different classes of molecular mediators. These mediators have a variety of functions, as discussed below.

■ Cytokines

Cytokines are small-molecular-weight glycosylated signaling molecules that are secreted by a number of different cell types with autocrine, paracrine, or endocrine directive activities.[94] The term *cytokine* includes many categories of molecular mediators including interleukins, interferons, and growth factors.[94] Cytokine secretion is usually a brief, self-limited event that requires preformed pools of intracellular cytokines and new mRNA and protein synthesis, which takes place over a matter of hours rather than seconds or minutes.[95] A variety of cytokines have been implicated in the regulation of airway inflammation and thus in the pathogenesis of asthma (Table 43-1).[96] The support for cytokine involvement in asthma was based on the detection of these mediators in the airways of patients with asthma, particularly in bronchoalveolar lavage fluid after allergen challenge and in situ hybridization of retrieved cells or biopsy materials.[97,98] In addition, effective treatment with monoclonal antibodies directed against pivotal T2 cytokines, that is, IL-5, IL-4/IL-13, have demonstrated clinical efficacy; these data indicate a likely role for these cytokines as risks for exacerbations, airflow obstruction, and symptoms (Table 43-2). The overall effect of the complex cytokine network in the airway depends on a number of factors, including the relative abundance of the cytokines, their ability to recruit and perpetuate the actions of inflammatory cells such as eosinophils and lymphocytes, and their ability to amplify or suppress inflammation by interacting with structural cells of the airway.

■ Chemokines

Chemokines are small-molecular-weight proteins, 8 to 12 kDa, that are classified into four categories based on the organization of specific cysteine residues in their protein sequence: XC, CC, CXC, and CX_3C.[99] The predominant function of chemokines is the recruitment or chemotaxis of inflammatory cells, and some chemokines have additional signaling functions.[99] There are corresponding families of chemokine receptors for each class of chemokine. Notably, there is considerable overlap and redundancy in the chemokines and their target receptors. Since the localization of inflammatory cells into the airway is dependent to a large extent on chemotaxis via chemokine signaling, chemokine receptors have become an attractive target for asthma therapy, but none has yet made it to the clinic. There are currently chemokine receptor inhibitors for CCR5 as well as others in development as potential therapy for asthma.[100,101]

■ IgE

The initial association of IgE with asthma was based on several epidemiologic studies that demonstrated increased levels of IgE in patients with asthma.[102–104] With the improved understanding of the role of mast cell mediators in the pathogenesis of asthma, the importance of IgE in triggering mast cell activation and airway inflammation was increasingly recognized. This led to the development of a humanized monoclonal antibody directed against IgE to treat patients with uncontrolled allergic asthma.[105] The antibody (omalizumab) was shown to be effective in the treatment of severe uncontrolled asthma, reducing exacerbations and allowing patients to reduce corticosteroid dosage.[106]

■ Leukotrienes

The leukotrienes (LT) are a family of lipid compounds generated by the metabolism of arachidonic acid via the lipoxygenase pathway (Fig. 43-5).[107] These compounds are typically not preformed and stored in cells for release upon activation; rather, they are rapidly synthesized following activation of the source cell. LTC_4, LTD_4, and LTE_4 are potent bronchoconstrictors that are produced by several cell types, including eosinophils and mast cells. In contrast, LTB_4 is a neutrophil attractant.[107] The leukotrienes are also able to increase mucus secretion in the airway and facilitate plasma leak and edema in the airway wall.[107,108] The leukotriene receptor antagonist montelukast is currently used in the treatment of asthma.[109] Although effective in some patients, the leukotriene modifiers are limited by their limited potency in some patients with asthma.[110]

Aspirin-exacerbated respiratory disease is associated with chronic rhinosinusitis and nasal polyps and underlying severe asthma. These patients are characterized by an underlying overproduction of cysteinyl leukotrienes, that is, urinary LTE_4, which is released in higher concentrations with nonsteroidal anti-inflammatory drugs (NSAIDs) that provoke a severe asthma attack.[111] In this syndrome, the mast cell is considered the primary source of cysteinyl leukotriene production.

■ Prostanoids

The prostanoids are a family of lipid compounds generated from the metabolism of arachidonic acid via the cyclooxygenase pathway

TABLE 43-1 Cytokines and Lipid Mediators in Asthma

Cytokines		
Cytokine	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
Interleukins		
IL-1	DCs, monocytes, macrophages, mast cells, B and T cells, neutrophils, endothelial cells, airway epithelial cells	*Basophils:* Increased production of cytokines and histamine *DCs:* Increased cytokine production, upregulation of MHC and co-stimulatory molecules *Macrophages:* Increased cytokine production *Mast Cells:* Increased cytokine production, degranulation, and survival *Neutrophils:* Increased survival and release of proteases *B Cells:* Increased antibody production *T Cells:* Increased proliferation—especially for T_H2 and T_H17 cells
IL-2	$CD4^+$ T cells	*T Cells:* Increased survival and proliferation, increased T_H2 cytokine production
IL-3	T cells, mast cells	*Basophils:* Increased survival and release of IL-4, IL-6, and histamine *Eosinophils:* Increased degranulation *Mast Cells:* Increased survival and histamine release *Hematopoietic Stem Cells*: Increased production of mast cells, basophils, neutrophils, eosinophils, macrophages, erythrocytes, megakaryocytes, and dendritic cells
IL-4	T cells, mast cells, basophils, eosinophils	*Airway Smooth Muscle Cells:* Increased airway hyperresponsiveness *Basophils:* Increased recruitment *Eosinophils:* Increased recruitment *Goblet Cells*: Increased mucus production *Mast Cells:* Increased recruitment, upregulation of FCεRI *B Cells:* Increased class-switching to IgE, upregulation of FCεRII *T Cells:* Increased recruitment, increased T_H2 differentiation, increased production of T_H2 cytokines, decreased differentiation of T_H1 cells, decreased IFN-γ production by T_H1 cells
IL-5	T cells, mast cells	*Basophils:* Increased proliferation, maturation, and functional activation *Eosinophils:* Increased proliferation, chemoattraction, maturation, functional activation, and degranulation
IL-6	Macrophages, DCs, mast cells, neutrophils, B and T cells, endothelial cells, airway epithelial cells	*T Cells:* Increased production of T_H2 cytokines, decreased differentiation of T_H1 cells, decreased IFN-γ production by T_H1 cells, promotes differentiation of T_H17 cells, downregulation of T_{Reg} cells
IL-7	Bone marrow stromal cells	*Eosinophils:* Increased activation and survival *B Cells:* Increased proliferation and survival *T Cells:* Increased maturation and survival
IL-8	Airway epithelial cells, neutrophils, eosinophils, monocytes/macrophages	*Eosinophils:* Chemoattraction *Neutrophils:* Chemoattraction
IL-9	T cells	*Mast Cells:* Increased recruitment and maturation, increased expression of proteases, upregulation of FCεRI *T Cells:* Increased growth and proliferation
IL-10	Monocytes/macrophages, B cells, T cells (specifically T_{Reg} cells)	*DCs:* Inhibits expression of co-stimulatory molecules thus inhibiting T_H cell activation *Eosinophils:* Inhibits survival, recruitment, and maturation *Monocytes/Macrophages:* Downregulates MHC class II expression, downregulates inflammatory cytokine production *T Cells:* Downregulates IFN-γ and IL-2 production by T_H1 cells and IL-4 and IL-5 production by T_H2 cells
IL-11	Airway epithelial cells, eosinophils, airway smooth muscle cells	*Airway Epithelial Cells:* Regulates proliferation *Macrophages:* Inhibits production of TNF-α, IL-1, IL-12 *B Cells:* Increases immunoglobulin production *T Cells:* Inhibits production of TH1 cytokines, increases IL-4 and IL-10 production
IL-12	Dendritic cells, B cells, macrophages	*NK Cells:* Increased IFN-γ production *T Cells:* Increased IFN-γ production, increased TH1 differentiation, decreased T_H2 and T_H17 differentiation

TABLE 43-1 Cytokines and Lipid Mediators in Asthma *(Continued)*

Cytokines		
Cytokine	**Cell Sources**	**Proposed Cell Targets/Functions in Asthma**
IL-13	Mast cells, T cells	*Airway Epithelial Cells:* Increased permeability, increased mucus production, production of inducible nitric oxide synthase *Airway Smooth Muscle Cells:* Increased airway hyperreactivity *Eosinophils:* Promotes migration and survival *Macrophages*: Activation and enhanced MHC class II expression *B Cells:* Increased class switching to and production of IgE
IL-14	T cells	*B Cells:* Increased proliferation, suppression of Ig secretion
IL-15	Monocytes/macrophages, DCs	*DCs:* Increased activation and survival, increased production of IFN-γ *Mast Cells:* Increased survival *Monocytes/Macrophages*: Increased phagocytic activity, increased production of IL-8, IL-12, MCP-1 *Neutrophils:* Increased survival and phagocytic activity, increased IL-8 production *NK Cells:* Increased maturation and survival, increased production of IFN-γ, TNF-α, and GM-CSF *T Cells*: Increased proliferation of memory CD8$^+$ T cells, increased proliferation of T_H17 cells
IL-16	T cells, airway epithelial cells, DCs, eosinophils, mast cells	*DCs:* Increased chemoattraction *Eosinophils:* Increased chemoattraction *Monocytes/Macrophages:* Increased chemoattraction, upregulation of MHC class II expression *T Cells:* Increased migration, maturation, and proliferation
IL-17	T cells, NK cells	*Airway Epithelial Cells:* Increased production of IL-6, IL-8, G-CSF, PGE 2 *Eosinophils:* Increased chemoattraction *Neutrophils*: Increased production from stem cells, increased chemoattraction
IL-18	DCs, monocytes, macrophages, neutrophils, airway epithelial cells	*Basophils*: Increased production of cytokines and histamine *DCs:* Increased cytokine production, upregulation of MHC and co-stimulatory molecules *Macrophages*: Increased cytokine production *Mast Cells:* Increased cytokine production, degranulation, and survival *Neutrophils*: Increased survival and release of proteases *NK Cells:* Increased IFN-γ production *T Cells:* Promotes T_H1 differentiation
IL-19	Monocytes	*T Cells:* Increased production of T_H2 cytokines and downregulation of IFN-γ production
IL-20	Monocytes	Unclear
IL-21	T cells	*B Cells:* Increased proliferation of IgA, IgG, IgM producing plasma cells and decrease in IgE-producing plasma cells *T Cells:* Increased differentiation into T_H17 cells, upregulation of T_H1 cytokine production
IL-22	T cells, NK Cells	*Respiratory Epithelial Cells:* Increased production of antimicrobial peptides
IL-23	DCs	*Macrophages:* Increased TNF-α production *T Cells:* Increased IL-17 production, promotion of T_H17 differentiation
IL-24	Monocytes, T cells	Unclear
IL-25	Airway epithelial cells, eosinophils, mast cells	*T Cells:* Increased production of T_H2 cytokines
IL-26	Monocytes, T cells	Unclear
IL-27	Macrophages, DCs	*T Cells:* Increased differentiation into IL-10-producing T_{Reg} and T_H1 cells, decreased development of T_H2 and T_H17 cells
IL-28 (IFN-λ2, -λ3)	DCs	Inhibits viral replication *DCs:* Increase ability to stimulate production of T_{Reg} cells
IL-29 (IFN-λ1)	DCs	Inhibits viral replication *DCs:* Increase ability to stimulate production of T_{Reg} cells
IL-31	T cells	*Airway Epithelial Cells:* Attenuates proliferation of epithelial cells
IL-32	NK cells, airway epithelial cells, T cells	*Macrophages:* Upregulation of proinflammatory cytokines *Airway Epithelial Cells:* Decreased production of proangiogenic factors

Leukotrienes		
Dihydroxy Acid Leukotriene (LTB4)	DCs, monocytes/ macrophages, neutrophils	*B Lymphocytes:* Increased expression of CD23, CD54, and CD105 *DCs:* Recruitment, increased skewing of T_H0 cells to T_H1 type *Eosinophils*: Recruitment *Mast Cells:* Recruitment *Monocyte/Macrophages:* Increased production of IL-6, TNF-α, MCP-1 *Neutrophils:* Recruitment and activation *Airway Smooth Muscle Cells:* Increased proliferation *T Lymphocyte:* Recruitment
Cysteinyl Leukotrienes (LTC4, LTD4, LTE4)	DCs, eosinophils, mast cells, monocytes/macrophages	*Airway Smooth Muscle Cells:* Bronchoconstriction *DCs:* Increased migration to lymph nodes *Endothelial Cells:* Increased vascular permeability and upregulation of adhesion molecules *Eosinophils:* Recruitment *Goblet Cells:* Increased mucus production *Mast Cells:* Increased production of IL-5, IL-8, TNF-α, and MIP-1β *Monocytes/Macrophages:* Increased production of MCP-1, TNF-α, and MMP-9 *T Lymphocytes:* Increased T_H2 immune response
Prostanoids		
PGD2	Mast cells	*Airway Smooth Muscle Cells:* Bronchoconstriction *Eosinophils:* Recruitment, increased degranulation *Monocytes/Macrophages:* Increased cytokine production *Neutrophils:* Inhibition of activation *T Lymphocytes:* Recruitment, increased production of T_H2 cytokines, inhibition of IFN-γ production
PGE2	Airway smooth muscle cells, airway epithelial cells, endothelial cells, macrophages	*Airway Smooth Muscle Cells:* Inhibition of allergen-induced bronchoconstriction *Eosinophils:* Inhibits recruitment *Monocytes/Macrophages:* Decreased cytokine production, downregulation of MHC class II expression *T Cells:* Decreased proliferation, decreased T_H2 cytokine production
PGI2 (Prostacyclin)	Endothelial cells, monocytes/macrophages	*Endothelial Cells:* Vasodilatation *Eosinophils:* Inhibition of recruitment *T Cells:* Increased IL-10 production
Thromboxane A2	Platelets, endothelial cells, monocytes/macrophages	*Airway Smooth Muscle Cells:* Bronchoconstriction *Eosinophils:* Recruitment

TABLE 43-2 T2-Directed Anticytokines: Effects on Asthma Exacerbations, Lung Function, and Need for Oral Corticosteroids (OCS) in Patients with Severe Disease

Agent	↓ Exacerbations	↑ Lung Function	OCS ↓	Comment
Omalizumab (IgE)	25%	±	–	Only anti-IgE drug
Mepolizumab (IL-5)	50%	+	++	Indication for EGPA
Reslizumab (IL-5)	50%	++	–	Weight-based dose (IV)
Benralizumab (IL-5R)	50%	++	++	q 8 weeks causes ADCC
Dupilumab (IL-4/IL-13)	50%	++	++	FeNO response biomarker

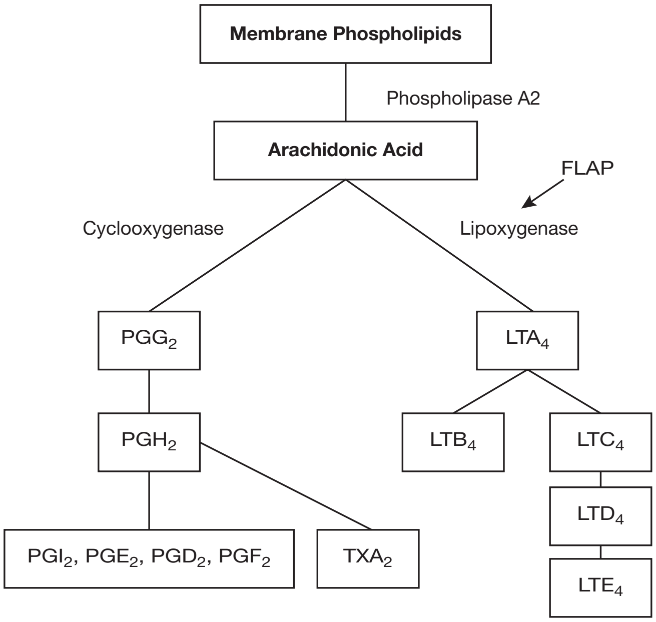

Figure 43-5 Formation of arachidonic acid metabolites. FLAP, 5-lipoxygenase activating protein; LT, leukotriene; PG, prostaglandin; TXA_2, thromboxane A2.

(Fig. 43-5).[112] Most of the prostanoids, that is, PGD_2, PGF_2, and TxA_2, are potent bronchoconstrictors and products of several cell types including eosinophils and mast cells.[112] In contrast, PGE_2 has bronchodilatory and anti-inflammatory activity.[113,114] The use of nonsteroidal anti-inflammatory medications to inhibit cyclooxygenase activity has not been shown to have an appreciable effect on airway inflammation to date. However, since PGD_2 is the predominant prostanoid involved in asthma,[115] specific PGD_2 receptor antagonists have been studied but failed to show exacerbation reduction in asthma.[116–119]

■ Nitric Oxide

The role of nitric oxide (NO) in the pathogenesis of asthma remains unclear. NO is continually synthesized at low levels in the airways of normal subjects. Sources of NO in the respiratory tract include airway epithelial cells (likely the primary source), smooth muscle cells, sensory nerves, endothelial cells, and macrophages.[120] At low levels, NO is a bronchodilator and vasodilator that antagonizes endothelin and has protective effects in the airway.[120] Higher levels of NO are found in asthma, secondary to increased inducible NO synthase (iNOS) expression that is induced by alarmins and cytokines such as TSLP and IL-13.[121] NO can react with superoxide anion in inflamed tissue to produce biologic oxidants that contribute to ongoing tissue damage and chronic asthmatic inflammation.[120] The production of NO is also thought to reflect the intensity or severity of airway inflammation. Thus, exhaled NO measurement has been utilized successfully as a tool to reflect the extent of airway inflammation as a measure of asthma control—in particular, the presence of eosinophils in the airway wall.[121]

■ Granule Proteins

Granulocytes, that is, mast cells, basophils, eosinophils, and neutrophils, all produce granular proteins that play significant roles in the pathogenesis of asthma.

Insights into the kinetics and importance of mast cell mediators were obtained from studies that measured BAL histamine and tryptase.[122] These studies demonstrated that mast cell activation is an early event: elevated BAL histamine and tryptase levels are seen 12 min after endobronchial antigen challenge. The levels of tryptase return to normal 48 h after antigen challenge while the levels of histamine remain elevated after 48 h. This suggests that other cell types that produce histamine (e.g., basophils) are recruited and activated to produce histamine at these later points or that mast cells generate and continue to release histamine over time following an initial activation.[122] Furthermore, BAL of allergic asthmatic subjects had only moderately elevated levels of tryptase at baseline but higher concentrations of tryptase following antigen challenge.[122]

Histamine is capable of inducing bronchoconstriction, increasing vascular permeability to cause edema, and increasing mucus secretion.[123] The role of tryptase is not well established, although there are data to suggest that it can activate inflammatory cells such as eosinophils, mast cells, and epithelial cells by cleaving a family of protease-activated receptors (PARs) on the cell surfaces.

The best known eosinophilic specific proteins include major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPX). MPB is the principal protein constituent of eosinophil granules. It is toxic to epithelial tissues, induces airway hyperresponsiveness, and causes histamine release from basophils.[124] ECP is more cytotoxic to the epithelium than MBP and damages target cells by membrane pore formation.[125] EDN, as the name implies, damages myelinated neurons.[126] EPX has different effector functions compared with neutrophil and monocyte myeloperoxidases (MPOs); it causes LTC_4 and LTD_4 degradation and causes histamine release from mast cells.[127] Data suggest that the presence of EPX in airways indicates eosinophil activation, and that EPX may be the dominant granule-associated protein associated with tissue inflammation.[128]

The primary granules of neutrophils contain MPO and lysozyme as well as hydrolases and proteinases, which are important to tissue penetration by neutrophils.[129] The primary neutrophilic granular proteins are myeloperoxidases, best known as autoantigens associated with p–antineutrophil cytoplasmic antibody (p-ANCA)-positive vasculitis such as eosinophilic granulomatosis polyangiitis (EGPA, formerly known as Churg-Strauss syndrome). The release of MPO and neutrophil elastase enhances host defense functions but also causes tissue damage to normal tissues, including airway epithelium.[129] Secondary granules contain lysozyme and collagenases, which can also potentially damage airway tissue and contribute to airway remodeling.[129] Neutrophil granule proteins are considered toxic to airway epithelium and tissue.

REMODELING IN ASTHMA

As occurs in most chronic inflammatory disorders in which there is a chronic cycle of "injury-repair," irreversible structural changes occur in the airway in asthma that are collectively called "airway remodeling." Airway remodeling involves epithelial changes, smooth muscle hypertrophy and hyperplasia, increased angiogenesis, increased fibroblast/myofibroblast activity, and increased subepithelial fibrosis that affect the structure and function of the large and small airways of the lung.[130] Prolonged infiltration of inflammatory cells and the cytokines, chemokines, and growth factors that they generate contributes to these structural changes and leads to irreversible obstructive physiology noted in many patients with asthma. Clinically, these are patients who have persistent obstructive physiology after maximal treatment with corticosteroids and bronchodilators. A therapeutic intervention that can improve lung function in these patients remains a significant unmet need in the field of asthma.

As mentioned previously, airway epithelium serves not only as an anatomic barrier, but also as a key player in asthma pathogenesis. Defects in airway epithelium are ubiquitous in human asthma. When injury occurs, the repair process has been likened to a chronic wound, which may not heal normally as a result of repetitive and ongoing insults and may result in airway remodeling as discussed above.[131] As with other types of chronic wounds, epithelial cells attempt to heal by promoting the release of growth factors from the underlying mesenchyme. This, in turn, leads to increased extracellular matrix deposition, fibrosis, and hypertrophy and hyperplasia of airway smooth muscle cells.[132] This process has been likened to the function of the epithelial-mesangial trophic unit (EMTU), a key component of early lung morphogenesis that may become reactivated in chronic asthma.[132] The consequence of prolonged epithelial injury is a protracted release of proinflammatory alarmins, cytokines, and profibrogenic growth factors such as TGF-β. When this response is combined with the inflammatory milieu derived from immune cells recruited to the airway chronically, the result is chronic airflow obstruction that may not respond or only partially responds to pharmacologic treatment. It remains unclear if more precise treatment could reverse the chronic obstruction in these patients or if the airways are irreversibly remodeled.

PHENOTYPIC CLUSTERS IN ASTHMA

Several recent studies have begun to identify phenotypes, or subphenotypes, of asthma. These studies have confirmed that asthma is heterogenous disease and that there may be at least four different phenotypes of disease.[133,134] Specifically, studies by Haldar et al. in the United Kingdom used sputum eosinophilia, in addition to measurements of atopic status and symptoms, to identify phenotypes.[133] They identified multiple clusters of patients with concordant symptoms and inflammation but also patients who were highly symptomatic with very little eosinophilic inflammation and lacked evidence of atopic sensitization. Other subgroups fit a more "classic" pattern of asthma with evidence of eosinophilic involvement and atopic sensitization. Other clusters fell somewhere between the two. This study and others are probing the heterogeneity of the disease and discovering the reasons behind differences in disease course and response to conventional asthma therapy.[12,28]

CONCLUSION

Asthma is a complex inflammatory disease that is caused by the contributions of many different immune cells, structural cells, molecular mediators, and external factors to produce acute and chronic inflammation of the airway, airflow obstruction, and chronic symptoms. The study of these factors has led to a greater understanding and appreciation of the breadth of this disease, as well as its complexity and heterogeneity. It has also led to the realization that different phenotypes of asthma exist, and treatment of asthma based on a patient's predominant phenotype may soon be possible. Over the last decade, biologic therapeutics have been made to target specific inflammatory mediators in asthma. The fact that these treatments have not been universally successful speaks to the complexity of this disease and need for more discovery. As research delves further into the pathogenesis and pathophysiology of asthma, many more targets will emerge that reflect activation of pathways that will lead to novel therapies that will improve the lives of patients with asthma and our understanding of this chronic inflammatory airway disease.

CHAPTER 44

The Epidemiology of Asthma

Kathleen A. Lee-Sarwar
Scott T. Weiss
Augusto A. Litonjua

INTRODUCTION

Asthma is an extremely common clinical syndrome and the most common chronic disease in children.[1] Asthma affects approximately 235 million people worldwide[2] and nearly 25 million Americans.[3] In the United States, asthma accounts for over 10 million medical visits yearly.[4] The estimated total annual cost of asthma care in the United States from 2008 to 2013 was more than 80 billion dollars.[5] These costs include $50.3 billion in medical expenses, $29 billion due to asthma-related mortality, and $3 billion due to missed work and school days.[5]

In 2018, 22% of those afflicted with asthma were children under the age of 18 years,[3] and most cases of asthma begin in preschool age.[6] This propensity to become clinically apparent early in life belies the fact that asthma originates in utero as an abnormality of fetal lung development. Asthma has important consequences in childhood and may have important consequences for adult obstructive lung disease. In addition to having clear genomic and prenatal developmental components, asthma risk and prognosis are influenced greatly by exposures including respiratory viruses, indoor allergens, maternal tobacco smoke, and other physical and social aspects of the environment. The paradox of this illness is that despite important strides in understanding etiologic environmental factors and mechanisms of airway inflammation characteristic of the syndrome, its prevalence and clinical burden remain unacceptably high. Although asthma morbidity and mortality rates have been steady for several years and have declined slightly recently,[7] the rates are dramatically higher than 30 years ago and continue to be significant, particularly for urban minority groups, low-income populations, and children.

The purpose of this chapter is to describe trends in asthma epidemiology and to examine potential reasons for these trends. We discuss the epidemiology of airway hyperresponsiveness, which is more prevalent than asthma, and review clinical heterogeneity in asthma and the concept of asthma endotypes. Environmental risk factors for asthma are discussed, with special attention to the emerging role of the human and environmental microbiomes. We conclude with a review of asthma natural history and the implications of the current trends, especially with regard to health disparities.

DEFINITION, PREVALENCE AND MORBIDITY OF ASTHMA

In 2007, the National Asthma Education and Prevention Program Expert Panel Report 3 (NAEPPR3)[8] defined asthma as a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role, including mast cells, eosinophils, neutrophils, T lymphocytes, macrophages, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of coughing, wheezing, breathlessness, and chest tightness. These episodes are usually associated with widespread but variable airflow obstruction that is reversible either spontaneously or with treatment.

Because asthma is a clinical syndrome, there is no gold standard for its diagnosis. As such, physicians employ nonstandardized algorithms for making the diagnosis, such as a history of wheezing or a parental history of asthma in conjunction with evidence of obstruction on lung function testing and a favorable response to a bronchodilator to identify the asthmatic patient. Frequently, age, sex, and other patient characteristics such as smoking status or allergic sensitization may influence a physician's diagnosis.

In general, epidemiologic surveys have tended to rely on historic or questionnaire sources to identify patients with asthma. Asthma cases have been identified either by physicians or by surveys in which the definition of who is asthmatic has been left to the patients themselves, surrogates, or the report of the diagnosis having been made by the patient's physician. Clearly, each of these methods of identifying asthma patients has inherent weaknesses. One must, therefore, assume that some bias in the reporting of cases is present and that the biases in each method of gathering data are different.

Asthma Prevalence in the United States

The National Health Interview Survey (NHIS), a program of the Centers for Disease Control and Prevention (CDC), is an annual random population household interview survey that provides information on asthma prevalence in the United States. Its data demonstrate an almost doubling of asthma prevalence in the last two decades of the 20th century, from 3.2 per 100 population in 1981 to 5.5 per 100 in 1996.[9] In 1997 the NHIS questions and methodology were modified, limiting comparisons of prevalence before and after 1997. The most recent results from the CDC, which analyzed data from the NHIS through 2017, indicate a slower increase in asthma prevalence from 2001 through 2013, and a slight decrease since then from a maximum prevalence of 8.5% in 2011 to 7.9% in 2017[10] (Fig. 44-1). The prevalence in children under 18 years remains higher than in adults; in 2017, it was 8.4% in children compared with 7.7% in adults.[10]

Asthma prevalence trends over the lifespan differ between males and females. Males tend to have higher asthma prevalence during childhood, whereas sex ratios equalize in the pubertal years and females predominate throughout the rest of adult life. For example, in the United States, the prevalence for males under age 18 years in 2018 was 8.3% compared with 6.7% for females; however, in adults

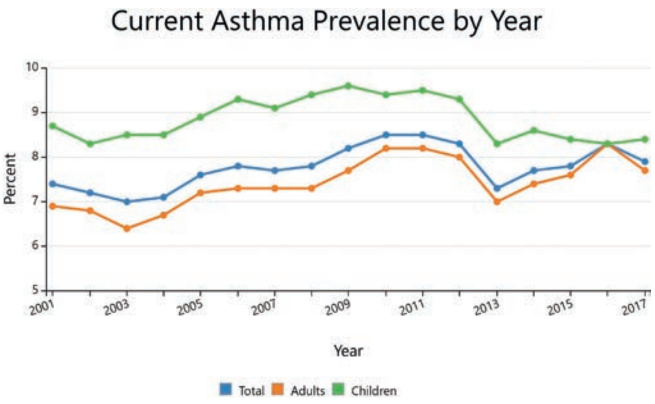

Figure 44-1 Current asthma prevalence figures from the National Health Interview Survey (NHIS), United States, by age group. *(Reproduced with permission from Centers for Disease Control and Prevention. Asthma Prevalence. www.cdc.gov/asthma/data-visualizations/prevalence.htm.)*

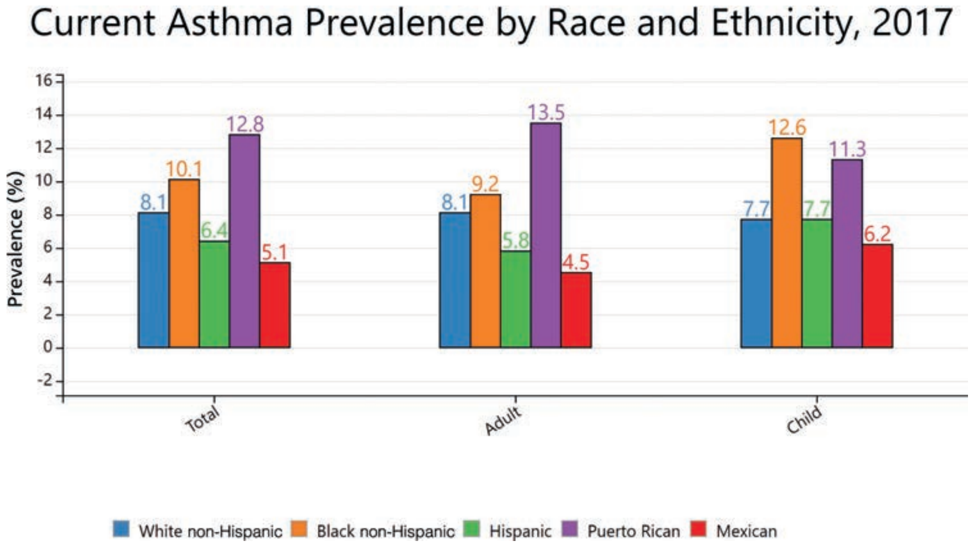

Figure 44-2 Current asthma prevalence figures from the National Health Interview Survey (NHIS), United States, by race and ethnicity and age group in 2017. *(Reproduced with permission from Centers for Disease Control and Prevention. Asthma Prevalence. www.cdc.gov/asthma/data-visualizations/prevalence.htm.)*

18 years and older, female prevalence (9.8%) is almost twice that for males (5.5%).[10] Thus, age and sex play important roles in modifying disease prevalence.

There is a striking difference in prevalence by racial/ethnic groups in the United States. The most recent data from 2016 to 2018 show that prevalence was 10.7% for black non-Hispanics, 6.5% for Hispanics, and 8.0% for white non-Hispanics.[3] It is noteworthy that the rate for Hispanics of Puerto Rican descent was very high at 14%.[3] In addition, there are marked differences in asthma prevalence by income group. Asthma prevalence was highest in 2018 among those below 100% of the poverty threshold (10.8%) and lowest among those in the highest income category, 450% of poverty threshold or higher (6.5%).[3] Figure 44-2 demonstrates these disparities using data from the United States in 2017.

Global Asthma Prevalence

Limited surveys have evaluated the global burden of asthma. The International Study of Asthma and Allergies in Children (ISAAC) used standardized surveys to determine asthma prevalence and severity in 6- to 7-year-old children in 61 countries and 13- to 14-year-old children in 97 countries between 2000 and 2003.[11] There was dramatic variation worldwide in prevalence of wheeze in the past 12 months. For example, current wheeze in 13- to 14-year-olds was reported in only 0.8% of respondents in Tibet but approximately one-third (32.6%) of respondents in Wellington, New Zealand.[11] There was a trend toward higher prevalence of current wheeze at higher-income study sites.[11] In contrast, among children with current wheeze, more severe symptoms were observed at lower-income study sites.[11]

The European Community Respiratory Health Survey (ECRHS) evaluated the prevalence, determinants, and management of asthma in 20- to 44-year-old adults from 48 centers, predominantly in Western Europe, with data reported through 1994.[12] Similar to the findings of ISAAC, ECRHS results showed marked differences in asthma prevalence between countries. Prevalence of wheeze ranged from a lower range of 4.1%–9.7% from centers in India, Algeria, and Italy to a higher range of 23.2%–32% from centers in Sweden, Denmark, Estonia, United States, United Kingdom, Australia, New Zealand, and Ireland.[12] The huge differences in asthma and wheeze prevalence between countries remains to be fully explained and likely reflects the large joint contributions of genetic and environmental factors on asthma risk.

Asthma Healthcare Utilization

The CDC in the United States collects information about physician office visits and emergency department visits from the National Center for Health Statistics and information about all-payer encounter-level hospital care data from the Healthcare Cost and Utilization Project. It also utilizes data from the National Ambulatory Medical Care Survey and National Hospital Ambulatory Medical Care Survey, which sample visits to office-based physicians, community health centers, and hospital emergency departments (EDs) and outpatient departments to evaluate medical service utilization.

Drawing from these sources, the rate of physician office visits for asthma declined among children under age 18 years from 2010 (776.8 per 10,000) to 2016 (332.9 per 10,000), while office visits for asthma remained stable among adults (372.0 per 10,000 in 2010 and 300.3 per 10,000 in 2016).[13] However, data from 2017 on ED visits and hospitalizations for asthma in the United States highlight that asthma still results in significant morbidity among the pediatric population and disproportionately affects this age group. Patients under age 18 years had more ED visits than adults: 85.3 per 10,000 compared with 38.3 per 10,000 population, and the rate was highest among those age 0 to 4 years: 139.6 per 10,000.[14] Similarly, children had more hospitalizations for asthma than adults (10.3 per 10,000 compared with 4.2 per 10,000), with the 0- to 4-year age group again having the highest asthma hospitalization rate at 17.2 per 10,000 population.[14]

The 2017 ED visit and hospitalization data for asthma in the United States also reveal staggering differences in healthcare utilization by race. There were 164.3 per 10,000 population ED visits and 13.1 per 10,000 hospitalizations for asthma among black individuals compared with 33.9 per 10,000 ED visits and 2.6 per 10,000 hospitalizations for asthma among white individuals.[14] These numbers indicate that ED visits and hospitalizations for asthma are five times more frequent in black individuals than white individuals in the United States.

Sex differences in asthma health care utilization are less striking. Males and females had similar rates of ED visits for asthma in 2017 (49.2 and 49.1 per 10,000, respectively), although hospital admissions for asthma were more frequent among females (6.5 per 10,000) than males (4.7 per 10,000).[14]

Trends in Asthma Mortality

Although asthma mortality rates are quite low, more than 3000 people die every year from asthma in the United States.[15] Recent data from 2001 to 2016 showed an encouraging decrease in the rate of death due to asthma from 15 per million to 10 per million.[15] The asthma death rate in 2016 was highest among adults age 65 years or older (29.2 per million); despite higher rates of pediatric ED visits and hospitalizations for asthma, individuals under age 18 years were nearly 5 times less likely than adults to die from asthma.[15]

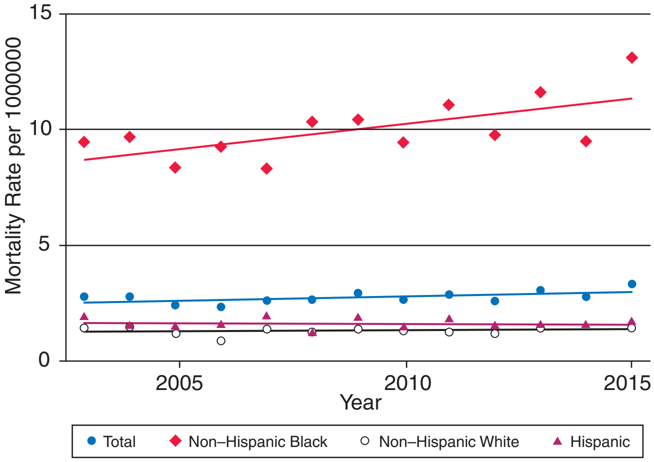

Figure 44-3 Pediatric asthma mortality rate in the United States by year among those age 3 to 19 years by race and ethnicity. *(Reproduced with permission from Arroyo A, Chee C, Camargo A, et al. Where do children die from asthma? National data from 2003–2015. J Allergy Clin Immunol Pract. 2017;6(3):1034–1036.)*

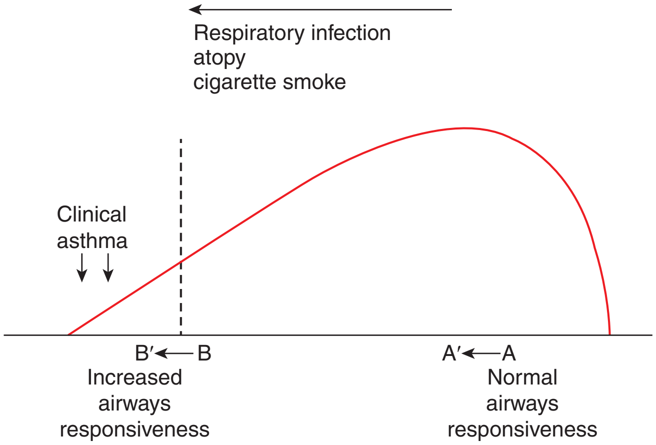

Figure 44-4 The effect of environmental exposures on the population distribution of airway responsiveness acting to move people in a more responsive direction. *(Reproduced with permission from Brown RW, Weiss ST. The influence of lower respiratory illness on childhood asthma: defining risk and susceptibility. Semin Respir Infect. 1991;6(4):225–234.)*

However, the downward trend in countrywide asthma mortality belies pockets of very high prevalence, morbidity, and mortality in certain populations. Between 2003 and 2015, there was actually an overall increase in deaths due to asthma among those under age 19 years, and non-Hispanic black children had an average annual mortality rate (10 deaths per million) 6 times higher than Hispanic children (1.62 deaths per million) and 7 times higher than non-Hispanic white children (1.33 deaths per million)[16] (Fig. 44-3). This disparity in asthma mortality between race groups in the United States has been observed since the 1980s.[17,18] While the absolute number of deaths due to asthma is very low, asthma mortality rates do represent a clear public health concern because almost all asthma deaths are preventable.

AIRWAY RESPONSIVENESS

Airway responsiveness is a defining characteristic of asthma and is both developmentally and environmentally determined. Airway responsiveness is measured by inhaling increasing doses of a bronchoconstrictor agonist, for example, methacholine or histamine, and repeatedly measuring lung function (usually FEV_1) after each dose. The dose of bronchoconstrictor that results in a 20% reduction in lung function from baseline is considered the provocative dose (or concentration), also called the PD or PD20. A low PD20 (usually less than 10 mg of methacholine) indicates significant airway responsiveness since the patient is responding to a low dose with at least a 20% drop in FEV_1.

Since flow in the airways is inversely proportional to the radius of the airway to the 4th power, small changes in airway size can have a big influence on PD20. An additional factor influencing the measurement is total lung size: the bigger the lung, the higher the PD20, and the less responsive the airway. These physiologic facts help explain some of the more relevant clinical correlates.

All individuals with active asthma have increased airway responsiveness, and it precedes and predicts asthma development,[19] but its presence in the general population exceeds the prevalence of asthma by about twofold.[20] This suggests that individuals genetically predisposed to develop increased airway responsiveness encounter relevant environmental stimuli such as viral illness, smoking, or occupational exposures and then increase their airway responsiveness and thus develop symptomatic asthma (Fig. 44-4).

Given the dependence on lung and airway size, airway responsiveness is highest at the extremes of age and in females at any given age.[21] It is known to be present at birth and correlates with gestational age, being greatest in preterm babies, which may explain why preterm birth is one of the strongest risk factors for childhood asthma.[22] In general, clinicians do not usually test for airway responsiveness in patients, preferring to infer the phenotype based on the presence of wheezing symptoms, and it is only in difficult cases where the diagnosis is in doubt that a test is required.

ASTHMA PHENOTYPES AND ENDOTYPES

Reversible airway hyperresponsiveness and inflammation are critical components of asthma pathogenesis. However, beyond these essential features, there is a wide range of clinical asthma phenotypes such that two individuals with asthma may dramatically differ in characteristics including age of asthma onset, disease severity, and comorbidities such as allergic sensitization and obesity. It is therefore now recognized that asthma is not a single disease.[23] Distinct clinical asthma phenotypes have been defined by applying analytic clustering techniques to data from large cohorts of subjects with asthma.[24–27] While methodologies and results have varied between studies, results largely converge around the existence of four phenotypes: early-onset mild allergic asthma, early-onset allergic moderate to severe remodeled asthma, late-onset nonallergic eosinophilic asthma, and late-onset noneosinophilic nonallergic asthma.[28]

While clinically intuitive, phenotypes do not map neatly onto specific disease mechanisms.[29] Just as distinct asthma phenotypes are now recognized, asthma *endotypes* have been proposed and are defined by divergent molecular and immunologic mechanisms.[30] The advent of the genomic era has enabled researchers to define asthma endotypes. The most widely recognized asthma endotyping concept categorizes individuals as having type 2 or non–type 2 asthma (Fig. 44-5). Approximately 50% of those with asthma fall into each of these categories.[31,32]

As has been recently reviewed,[22,33,34] type 2 inflammation involves activation of immune cells including T helper type 2 cells, type 2 innate lymphoid cells, eosinophils, and mast cells, as well as production of cytokines such as IL-4, IL-5, and IL-13 that together orchestrate allergic inflammation. Airway epithelial and stromal cells play a major role in the initiation of type 2 inflammation via production of IL-33, IL-25, and thymic stromal lymphopoietin (TSLP). This type of immediate hypersensitivity immune reaction is not specific to asthma and can be seen in other allergic diseases such as eczema,

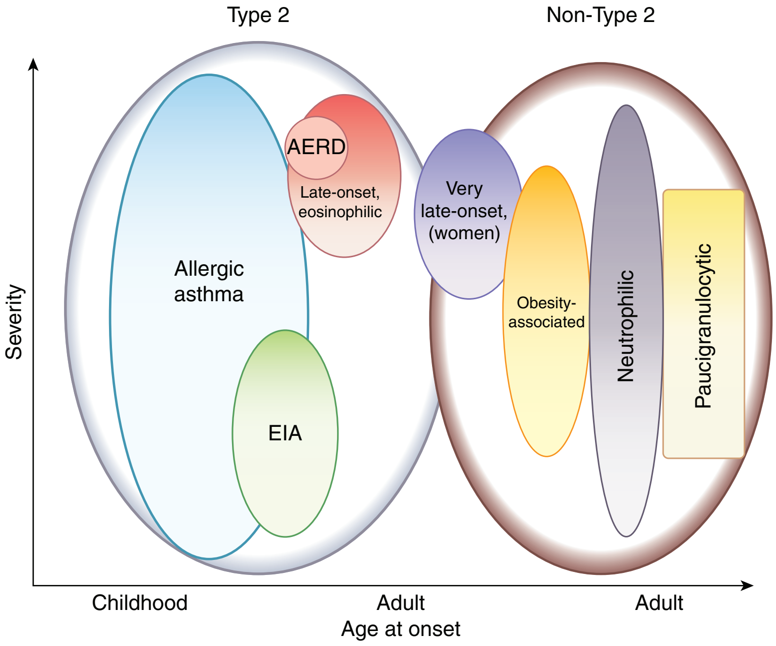

Figure 44-5 Theoretical grouping of asthma phenotypes based on the distinction between type 2 or non-type 2 asthma endotypes, age of onset and severity. Type 2 asthma consists of both early- and later-onset disease over a range of severities. Later-onset eosinophilic asthma and aspirin-exacerbated respiratory disease (AERD) are more likely to be severe, whereas exercise-induced asthma (EIA) is a milder form of type 2 asthma. Non-type 2 asthma includes very late-onset and obesity-associated asthma as well as neutrophilic asthma, and asthma in which affected individuals show little inflammation (paucigranulocytic). The intensity of the colors represents the range of severity, and the relative sizes of the subcircles suggest relative proportions of affected individuals. *(Reproduced with permission from Wenzel SE. Asthma phenotypes: the evolution from clinical to molecular approaches. Nat Med. 2012;18(5):716–725.)*

allergic rhinitis, and food allergy. Details on immune perturbations in asthma are provided elsewhere in this text (Chapter 43). Early-onset allergic asthma, eosinophilic asthma, and exercise-induced asthma all fall into the category of type 2 asthma, which is frequently accompanied by aeroallergen sensitization and may develop as sequelae of repeated viral infections in early life.

In contrast, non–type 2 asthma can be defined by the absence of type 2 inflammation.[35] Non–type 2 asthma encompasses heterogeneous mechanisms and may involve activation of cells such as T helper type 1 or 17 cells and neutrophils and production of cytokines such as IL-6, IL-8, IL-1β, and interferon-γ.[23,32] Neutrophilic asthma and paucigranulocytic asthma fall into the category of non–type 2 asthma, and those with non–type 2 asthma may have more severe disease.[23,35]

Obesity-related asthma also tends to fall in the category of non–type 2 asthma. This phenotype commonly begins in childhood and is associated with frequent asthma exacerbations.[36] A mechanical effect is postulated to be the result of decreased tidal volume and decreased functional residual capacity in obesity.[37] However, the critical links between obesity and asthma involve more than mechanical effects and may be related to shared genetic susceptibilities, events during fetal development, comorbidities such as gastroesophageal reflux disease, shared environmental exposures such as pollution, or common dietary and microbiome perturbations.[36,38] Immune effects may also contribute to obesity-related asthma; for example, proinflammatory cytokines can be induced or produced by adipocytes.[39] Clearly, much remains to be learned about the endotypes underlying obesity-related asthma.

Several biomarkers have been identified to differentiate asthma endotypes. Sputum cell counts are frequently used to ascertain the degree and type of asthmatic inflammation, with major categories including eosinophilic, neutrophilic, mixed granulocytic, and paucigranulocytic.[40,41] Other biomarkers of type 2 asthma include peripheral eosinophilia, elevated total IgE, and presence of allergic sensitization.[33,34] Fractional excretion of nitric oxide (FeNO) is another relevant biomarker:[42] enzymatic production of nitric oxide in the lower airway is induced by type 2 inflammation,[43] and elevated FeNO is associated with eosinophilic inflammation[44] and asthma severity.[45,46] Although less available outside of research settings, evaluation of microRNA and gene expression has been performed for endotype discovery and led to recognition of bronchial periostin expression as a type 2 asthma biomarker.[47]

Like asthma phenotypes, the asthma endotype concept has limitations. A single person with asthma may exhibit multiple contributory molecular and immunologic mechanisms or may exhibit some but not all of the characteristics of a specific endotype. For example, many individuals with asthma exhibit eosinophilia but do not have comorbid allergic sensitization or disease.[28] Additionally, different studies have used different input data types and statistical methods to define endotypes. As a result, there is no consensus endotyping schema, endotype groups necessarily overlap, and individuals with asthma are frequently not easily categorized. It is highly likely that the use of multiomic data may lead to more robust endotyping in the not-too-distant future.

Nonetheless, the endotyping concept has been critical for the development of treatments that target specific disease mechanisms, as has been reviewed.[28,34] Endotype-tailored drugs currently available for moderate and/or severe type 2 asthma include the anti-IgE omalizumab for those with evidence of allergic sensitization; the anti–IL-5 agents mepolizumab, benralizumab, and reslizumab for those with an eosinophilic phenotype; and anti-IL4ra dupilumab for those with an eosinophilic phenotype or oral corticosteroid dependence. Non–type 2 asthma is associated with poor response to glucocorticoid treatment,[35] and fewer treatments have been identified as beneficial in non–type 2 asthma, although macrolide antibiotics may be effective.[48] This topic is discussed in detail in Chapter 45.

THE ROLE OF THE MICROBIOME

The microbiome refers to the collective genomic contents in a particular environment, while the microbiota refers to the specific organisms resident in that environment.[49] The human microbiota has the capacity to profoundly influence its biochemical environment, and it has several known essential functions including nutrient harvest, vitamin synthesis, and development and maintenance of immune function.[50–53] Germ-free mice have reduced T regulatory cells, elevated IgE, and increased susceptibility to anaphylaxis and allergic inflammation, indicating a key role of the microbiome in asthma and allergic pathophysiology.[54]

Findings from germ-free mice dovetail with the concept originally framed as the “hygiene hypothesis,” which posited that reduced microbial exposure is responsible for the increased prevalence of allergic disease observed in countries like the United States. This was first proposed via an observation in 1989 that larger household size is associated with reduced hay fever[55] and has evolved into a "microbiota hypothesis" whereby a variety of early-life risk factors impact microbiome composition and thereby increase risk of allergy and asthma. Since asthma has its beginnings in early life, investigation into factors that influence the composition of the early life microbiome is intensifying. Environmental and lifestyle factors that are known to affect the microbiome and that have been linked to reduced risk of asthma and allergies include breastfeeding, living on a farm, owning a dog during infancy, birth by vaginal delivery, daycare attendance, and absence of antibiotic treatment.[56,57] Thus, environmental exposures may act through changes in the composition of the microbiome to bring about disease. The concept of "dysbiotic drift," whereby modern environmental forces drive microbial dysbiosis in a way that disproportionately impacts socioeconomically disadvantaged populations, could be a unifying hypothesis on the origins of asthma and health disparities.[58,59]

There are four major mechanisms whereby microbes could impact disease risk. First, pathogenic microbes can directly cause or worsen disease; for example, upper respiratory viral illnesses are well-known causes of wheeze and asthma exacerbations.[60] A second mechanism, discussed further below, is microbial production of bioactive metabolites. A third mechanism is elaboration of pathogen-associated molecular patterns that can directly engage with host receptors such as Toll-like receptors. For example, the amount and strength of Toll-like receptor engagement by fecal microbial lipopolysaccharides are associated with asthma and autoimmune diseases.[61] Finally, specific microbes can contribute to colonization resistance, whereby pathogenic microbes have reduced ability to establish a niche; or groups of microbes with complementary functions could form communities and together impact disease risk.[62] The role of this last mechanism is less well-established in asthma.

Both microbes present in the human host and in the surrounding environment have been associated with development of asthma and with existing asthma. These findings are discussed in this section and depicted in Fig. 44-6.

The Airway Microbiome

Although fungi and archaea are likely to play a role in asthma development, viruses and bacteria have been studied more extensively. Viruses have a well-established role in asthma development, with respiratory syncytial virus (RSV) and rhinovirus in particular implicated as causes of early-life wheeze that predispose to subsequent asthma.[60,63] RSV is the major cause of bronchiolitis in children, and RSV infection is associated with IgE production, airway inflammation, and increased airway responsiveness. Human rhinoviruses, which are more common causes of upper and lower respiratory infections than RSV, also may cause bronchiolitis;[64] rhinoviruses, especially of the rhinovirus-C serotype, have been associated with asthma onset.[65] Respiratory tract infections by parainfluenza viruses, influenza virus, and human metapneumovirus during infancy are all also associated with childhood wheezing.[63]

It is hypothesized that susceptibility to asthma associated with viral infection in early life results from the interaction of developmental, genetic, and environmental factors. In particular, the progression from wheezing with viral illness to subsequent asthma has been linked to the atopic march, as children with pre-existing atopy are at highest risk of asthma after a rhinovirus wheezing illness, perhaps in part due to the inhibitory effects of Th2 inflammation on antiviral immune responses.[65] Jackson and colleagues[65] showed that while human rhinovirus was the dominant factor in developing asthma by the age of 6 years, the risk was highest when concomitant allergic sensitization was present. This concept is supported by evidence that treatment with the anti-IgE monoclonal antibody omalizumab increases IFN-α production in rhinovirus-treated peripheral blood mononuclear cells and, in children with asthma, resulted in reduced frequency and duration of rhinovirus infection and reduced frequency of asthma exacerbations.[67,68]

In addition to their role in asthma development, viral respiratory illnesses trigger asthma exacerbations and induce nonspecific increases in airway responsiveness and airway obstruction.[69,70] A number of studies have demonstrated a close temporal relationship at the individual and population levels between viral infections and asthma exacerbations, and they have demonstrated that those with asthma may have increased susceptibility to viral lower respiratory infections.[71,72]

In contrast to viral infections, bacterial infections are not associated with asthma exacerbations,[73] and the relative importance of the bacterial versus viral airway microbiome in asthma development has not yet been determined. The lower airway was previously thought to be sterile under normal conditions, but now it is known to be colonized, most likely with microbes that originate in the upper airway and oropharynx. Studying the airway microbiome is challenging for multiple reasons. For example, it is not clear which anatomic compartment along the airway is most relevant, contamination is more of a consideration when sampling low-biomass areas such as the lower respiratory tract, and treatments such as inhaled steroids can influence airway microbiome composition.[74]

Studies in children most often utilize upper airway samples such as nasal or oropharyngeal swabs to study the airway microbiome. Longitudinal cohort studies have found that colonization early in life with *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae* is associated with subsequent recurrent wheeze.[75] These taxa and other bacterial microbiome perturbations have also been associated with RSV, rhinovirus, and lower airway symptoms during respiratory infections,[76–79] raising the question of whether these bacteria have causal importance or are simply associated with pathogenic viruses.

In addition to impacting asthma development early in life, airway microbiome perturbations have been observed in children and adults with existing asthma. In particular, Proteobacteria, including the genus *Haemophilus*, is enriched in the airways of subjects with asthma.[80–83] The impact of the microbiome on asthma phenotypes, endotypes, and responses to treatment is an area of active research. Several studies have demonstrated differences in the airway microbiome between asthmatic subjects with sputum eosinophilia and those with sputum neutrophilia, or in association with blood eosinophilia.[83–87] Airway microbiome composition has been associated with other disease-related features, including airway hyperresponsiveness, lung function, and Th17-related gene expression.[83,84,88,89] Microbiome alterations may also inform response to asthma pharmacologic treatments. Of particular interest, corticosteroid resistance has been associated with airway microbiome features including enrichment of *Haemophilus parainfluenzae*.[90,91]

The Environmental Microbiome

A landmark study of the impact of the environmental microbiome on asthma compared Amish farmers from Indiana and Hutterite farmers from South Dakota.[92] These populations are genetically similar, but Amish people live in closer proximity to animal dwellings including cow stables compared to Hutterites. Interestingly, Amish children have a fourfold lower prevalence of asthma compared with Hutterites. Dust collected from Amish homes had higher perennial allergen levels, higher endotoxin levels, and different bacterial compositions compared with dust from Hutterite homes. These differences in environmental microbial exposures could contribute to differences in asthma risk. In a mouse model of OVA-induced allergic asthma, intranasal treatment of mice with

Clin Rev Allergy Immunol. 2019;57(3):350–363.)*

Amish house dust abrogated airway resistance. The protective effect of Amish house dust was reduced in MyD88 and MyD88-Trif knockout mice, demonstrating a dependence on innate immune pathways such as Toll-like receptor activation.[92] Based on this and other studies,[93,94] there is compelling evidence for a protective effect of farm environments with a key role for innate immune activation, although the specific microbes and mechanisms at play are not fully defined. Exposure to a wider array of microbial agents via farm animals and ingestion of raw, unpasteurized milk have been postulated to mediate the effects of early life exposure to farming environments,[92,95] and it may also affect the development of the child's intestinal microbiome.[96]

Other factors are likely to impact the environmental microbiome with relevance for asthma risk. For example, although existing asthma is associated with allergic sensitization to cats and dogs,[97] living with a dog during infancy has been associated with reduced risk of subsequent asthma or wheeze.[98,99] The connection between dog ownership and asthma may be mediated by changes to the household microbiome, as pets contribute significantly to household endotoxin levels.[100,101] While a pooled analysis of 11 European birth cohorts did not find any effect of pet ownership on asthma and allergic rhinitis in school-age children,[102] it is likely that there are subsets of children for which early exposure to dogs and other pets may be helpful.[103] The protective effect of early-life dog exposure is in contrast to the effects of early exposure to other indoor allergens, such as dust mite, which is associated with increased risk of subsequent asthma as discussed in "Indoor and Outdoor Allergens," below.[104,105]

The Gut Microbiome

Although distant from the lung, the gut harbors the most numerous and diverse collection of microbes in the human body, and microbial activity in the gut can have effects in organs throughout the body.[106] Data from several birth cohort studies demonstrate that differences early in life in gut microbiome composition can be detected between children who subsequently develop asthma and those who do not.[107–110] These differences have been seen in the first months of life, but not later,[108,109] suggesting a transient "window of opportunity" for the microbiome to impact asthma risk. In contrast to the numerous published studies on the gut microbiome in early life and development of asthma, little is known about the gut microbiome in existing asthma. In one of the few studies on this topic, an increased abundance of histamine-secreting fecal microbes was found in adults with asthma compared to healthy controls.[111]

Gut microbial metabolites are felt to be major mediators of the link between gut bacterial composition and asthma risk. Short-chain fatty acids are a class of metabolites that include acetate and butyrate and have been well studied in the context of asthma. Short-chain fatty acids are derived from bacterial fermentation of dietary fiber and have several health effects including tolerogenic effects on multiple facets of immune function.[112] Both animal and human cohort studies have provided evidence of a protective effect of short-chain fatty acids on asthma development.[108,113–115]

12,13-diHOME, a metabolite of the omega-6 fatty acid linoleic acid, also plays a role in asthma development. 12,13-diHOME is enriched in stool samples from infants at risk of subsequent asthma and atopy.[109] In mouse models, peritoneal injection of 12,13-diHOME increases airway inflammation and IgE and reduces lung T regulatory cells.[116] A subset of gut microbes, but not human cells, express epoxide hydrolases that are required in the production of 12,13-diHOME; genes that encode these enzymes are present in higher abundances in stool samples from infants at risk of asthma and atopy.[116] Other classes of microbial-derived metabolites likely impact asthma risk or morbidity, including other polyunsaturated fatty acids, tryptophan metabolites, and bile acids.[117]

GENETIC SUSCEPTIBILITY AND GENE-ENVIRONMENT INTERACTIONS

Asthma is considered a complex disease that has both genetic and environmental determinants. Since the completion of the Human Genome Project in 2000, more than 100 genes have been directly linked to asthma through association studies. These studies look at single nucleotide polymorphisms (SNPs) across the genome and relate them to asthma occurrence using either a case-control or a family-based design. These genome wide association studies utilize the association of SNPs with each other, that is, their correlation, or linkage disequilibrium, to cover the whole genome by analyzing a subset of SNPs. While these studies have a variety of threats to their validity, through increasing sample size and replication, many genes for asthma have been identified.[118,119]

In 2007, in the second GWAS study ever performed, a locus on chromosome 17q21 was identified as being associated with asthma.[120] This was replicated in multiple other studies and seemed to be strongest for childhood asthma and asthma onset.[121] The locus is complex, as there are at least five genes—ORMDL3, GSDMB, GSDMA, ZPBP2, and IKZF3—that are tightly correlated with each other in the region.

Most of the initial functional work has focused on ORMDL3 and GSDMB. In 2009, a causal functional variant at this locus, rs12936231, was identified. This SNP is predicted to disrupt the binding of an insulator, CTCF, in ZPBP2 and is correlated with expression of both ORMDL3 and GSDMB.[122] In 2016, a second SNP, rs4065275, in the locus on the same haplotype was demonstrated to have a similar functional effect and was tied to IL-2 levels.[123]

Another important feature of the genetic epidemiology of the 17q21 locus is that a variety of environmental factors, including vitamin D, tobacco smoke, antibiotics, furry pets, inhaled corticosteroids, and viral respiratory illness, all interact with this locus, suggesting that it might be central to the origin of asthma.[121]

Much recent work has been done to determine the functional effect of the genes in the 17q21 locus on asthma and how they interact with the environment. Mice expressing the ORMDL3 transgene exhibited spontaneous increases in airway hyperresponsiveness, associated with airway wall remodeling and peribronchial fibrosis and airway smooth muscle hypertrophy without airway inflammation.[124] ORMDL3 is known to inhibit the enzyme serine palmitoyltransferase, the rate-limiting step in sphingolipid production.[125] In accordance with this, siRNA knockdown of ORMDL3 in human bronchial epithelial cells led to increased sphingolipid pathway metabolites,[124] and ORMDL3-overexpressing transgenic mice were found to have reduced levels of sphingolipids.[126]

Recently ORMDL3 genetics were combined with metabolomics to strengthen this association in human studies. Non-atopic childhood asthmatics were shown to have lower levels of circulating sphingolipid metabolites, and these lower levels were linked to SNPs (rs7216389 and rs8076131).[127] These SNPs are eQTLs (expression quantitative trait loci) that are correlated with ORMDL3 expression. Other recent work showed that the genetic locus was rich in vitamin D receptor binding sites and that vitamin D levels interacted with the causal rs12926321 SNP to determine childhood asthma susceptibility, that both mother and child genotypes at this locus were relevant to genetic risk, and that both vitamin D and the ORMDL3 SNP rs12926321 were linked to sphingolipid levels.[128] To summarize this portion of a complex and still developing story, higher ORMDL3 expression is associated with lower sphingolipid levels and increased airway hyperresponsiveness, and hence higher asthma risk. Vitamin D can downregulate ORMDL3 expression and also has a direct effect to increase sphingolipid levels and hence decrease asthma occurrence. This effect was observed in both white subjects and African-Americans.[128] Of note, African Americans have lower vitamin D levels than other Americans.[129]

Much work still needs to be done on this locus, including on GSDMB and how viral illness interacts with the locus to produce childhood asthma, as well as elucidating how the other approximately 100 known asthma loci contribute to disease development. However, the beginning outlines of how genes and environmental factors interact to cause asthma are now clear, and 17q21 is a central part of this story.

ENVIRONMENTAL RISK FACTORS

Below we present some of the most important environmental risk factors for the development or exacerbation of asthma not discussed earlier.

Perinatal Factors

Asthma originates in utero as an abnormality of fetal lung development. As such, several perinatal factors impact asthma risk. Prematurity is one important factor that carries an increased risk for the development of asthma. A meta-analysis showed that infants born at less than 37 weeks' gestation are at greater risk for developing asthma than term infants.[130] More recently, it was shown that the risk for asthma is likely mediated through the effects of prematurity on the development of obstructive lung function deficits.[131]

Prematurity is also associated with bronchopulmonary dysplasia,[132] a disease characterized by increased airway responsiveness and asthma symptoms. Some investigators have found that low birth weight independent of prematurity has been associated with asthma risk.[133,134] The strength of the association between prematurity and/or low birth weight on asthma or asthma symptoms appears be greatest in very young children, and the effects decrease over time.[135,136] Note that black individuals have higher rates of prematurity than white individuals; thus, prematurity may contribute to racial differences in asthma prevalence and morbidity. Despite much research, there is no conclusive evidence that breastfeeding influences atopic sensitization or the development of asthma.

Recent studies have focused on maternal diet during pregnancy and its effect on the development of asthma and allergies, with the hypothesis that nutritional deficiency or excess may lead to programming of the fetus for adult disease.[137] These studies have mostly used nutrient intake estimates derived from food frequency questionnaires that assess how often a particular standard serving of a food or drink is eaten. The responses to the questionnaire, in conjunction with a database of nutrient composition of foods, are then used to calculate the amount of a particular nutrient over a specified time period.[138] A few studies have measured the particular nutrient in either maternal or cord blood samples. A meta-analysis found that there was weak support for protective effects of higher maternal intakes of vitamin A, D, E, and zinc for the prevention of asthma in children.[139]

Vitamin D

In the strict sense of the word, vitamin D is not actually a vitamin, since humans are able to produce the compound in the skin on exposure to UVA rays from the sun. While the first report of an effect of vitamin D on asthma and allergies appeared in 1934,[140] research into the effects of vitamin D did not begin in earnest until the last decade. There are two opposing hypotheses regarding the role of vitamin D in asthma. Wjst and Dold suggested that fortification of food with vitamin D and the widespread use of multivitamins in childhood contributed to the rise in asthma and allergies.[141] On the other hand, given the documented decrease over time in the levels of the circulating form of vitamin D in population studies,[142] Litonjua and Weiss hypothesized that the increasing prevalence of vitamin D deficiency led to the increase in asthma prevalence worldwide.[143]

Many epidemiologic studies have investigated the role of vitamin D in the development and control of asthma. With regard to the development of asthma and allergies, most studies have investigated either estimated maternal intakes of vitamin D from foods and supplements or maternal levels of 25-hydroxyvitamin D (25OHD). Four observational cohort studies have reported beneficial effects of a higher maternal intake of vitamin D in pregnancy on outcomes in their children.[144–147] However, other studies have not replicated these findings.[148–151] Two clinical trials of vitamin D supplementation in pregnancy have been completed.[152,153] While neither study on its own showed a statistically significant effect, a combined analysis showed a significant protective effect of maternal vitamin D supplementation on early wheezing and asthma by age 3 years.[154] The protective effect, however, did not persist through age 6 years.[155] It is likely that there are subsets of early wheezing phenotypes that may respond to vitamin D supplementation in utero, and further studies will be needed to determine this. Additionally, both clinical trials performed vitamin D supplementation only in pregnancy. There may be additional effects of postnatal vitamin D supplementation for asthma and wheeze prevention.[156]

As for the role of vitamin D in asthma control and management, observational studies have shown that asthmatics with higher circulating vitamin D levels have greater lung function,[29,30] lower risks for exacerbations,[157,158] and generally less severe indices of disease.[159] An initial small trial of 48 children with newly diagnosed asthma showed that vitamin D supplementation led to a significant reduction in the number of exacerbations over a period of 6 months.[160] Subsequent larger studies in adults and children[161] with chronic asthma did not show an effect of vitamin D supplementation in the prevention of asthma exacerbations.

Omega-3 Fatty Acids

Omega-3 and omega-6 fatty acids are major forms of polyunsaturated fatty acids (PUFA). The essential fatty acids alpha-linolenic acid and linoleic acid are the simplest members of the omega-3 and omega-6 fatty acid families, respectively.[162] Dietary PUFAs are critical sources of bioactive metabolites and cell membrane phospholipid components: alpha-linolenic acid metabolites include eicosapentaenoic acid and docosahexaenoic acid, and linoleic acid metabolites include arachidonic acid. Diet is a major determinant of the proportions of omega-3 and omega-6 metabolites. Major food sources of omega-3 fatty acids include oily fish such as salmon, mackerel, and herring.

Omega-3 PUFAs are generally thought to be anti-inflammatory, while omega-6 PUFAs contribute to inflammation.[163] During the course of the 20th century, changes in the Western diet led to increases in consumption of omega-6 over omega-3 PUFAs, primarily due to increased consumption of linoleic acid–rich soybean oil.[164] This shift has been proposed as a potential cause of the increased occurrence of allergic disease over the past half century.[165]

With regard to asthma prevention, a trial of fish oil (omega-3 PUFAs) versus placebo (olive oil) was recently completed. The trial showed that supplementation of 2.4 g of omega-3 PUFAs beginning at 24 weeks of gestation decreased the risk for persistent wheeze or asthma at 3 years of age. This trial was notable for the high dose of PUFA used as the intervention. Prior prenatal omega-3 PUFAs supplementation trials using lower doses (400 mg[166] and 800 mg[167]) did not show an effect on childhood lung function or allergic outcomes, respectively. With regard to the role of omega-3 PUFAs in established asthma, a trial of fish oil supplementation (4 g/day) in obese asthmatics did not show any difference in asthma control when compared with placebo.[168]

■ Indoor and Outdoor Allergens

Indoor allergen sources include animals (cats, dogs, rodents); insects (mites, cockroaches); and fungi. For many decades, the prevailing hypothesis of early asthma development was that it was caused by exposure to allergens, particularly house dust mite allergens.[104,169] Allergens are well-known precipitants of asthma exacerbations and increased morbidity.[170,171] However, studies of trials of allergen reduction or avoidance have not produced definitive results. A Cochrane meta-analysis of 54 trials using varying methods of mite-allergen reduction (physical methods, chemical methods, and a combination) concluded that there was no clinical benefit of dust mite allergen reduction.[172] Factors that could explain these findings include that adherence to the demanding protocols for control of allergen exposure is difficult and may not always result in sufficient reduction in personal aeroallergen exposure, and that allergens are ubiquitous in other settings outside the home (e.g., schools and daycare[173]). Evidence that exposure to some sources of indoor allergens, such as dogs, in early life may actually be protective against asthma development is discussed in "Role of the Microbiome," above. It is likely that mechanisms are complex, and that exposure to a wide array of microbes related to dogs may override the effects of exposure to dog allergen.

Outdoor allergens include trees, grass, and weed pollen constituents. The evidence for outdoor allergen exposure relates to asthma morbidity rather than asthma development. Susceptible individuals may have increased asthma symptoms at times of pollination.[174] Assessment of sensitization to indoor and outdoor allergens is part of the management of asthma, as is monitoring of levels of outdoor allergens.[175]

■ Smoking, Second-hand Tobacco Smoke Exposure, and E-cigarettes

Maternal cigarette smoking is a major risk factor for the development of asthma in the first year of life. Both a meta-analysis[176] and a pooled analysis[177] showed that the risk of developing asthma ranges from around 40% to 85% greater among children born to mothers who smoked during pregnancy versus children born to mothers who did not smoke. This effect appears to be strongest in children who developed asthma before 2 years of age.[176]

Second-hand smoke exposure exacerbates asthma in children of all ages.[178] Wilson and coworkers evaluated a cotinine-feedback behavioral intervention administered to caregivers that successfully reduced second-hand smoke exposure and health care utilization by children with asthma at 1 year follow-up.[179] However, in a follow-up study, the effect was seen only in the children at highest risk for exacerbation.[180] In adults, cigarette smoking is associated with the development of airway hyperreactivity.[181] Whether this hyperreactivity represents asthma or COPD can be difficult to determine. Cigarette smoking and asthma produce a synergistic and accelerated decline in lung function.[182,183] Additionally, the response to corticosteroid therapy used for asthma is reduced in active smokers.[182]

In recent years, the prevalence of electronic cigarette (e-cigarette) use has increased to epidemic proportions. E-cigarettes are electronic devices that heat a liquid and produce an aerosol or a mix of small particles in the air. They are known by many different names including "e-cigs," "vapes," "vape pens," and "electronic nicotine delivery systems (ENDS)." Epidemiologic studies have shown an increased risk for asthma among e-cigarette users.[184]

■ Other Pollutants

Outdoor pollutants implicated in the development or exacerbation of asthma include ozone, sulfur dioxide, particulate matter, and components of motor vehicle exhaust.[185,186] Measuring exposure to potential pollutants is difficult, and correlating exposure with symptoms and exacerbations of disease is very expensive. Most monitoring of pollutants is from fixed external stations. Sometimes proxy measures of pollutant exposure, such as traffic counts, are used. Although potentially more accurate, monitoring of personal exposures is particularly difficult and expensive.[187] Assessing which of the many possible simultaneous outdoor inhalants affects asthma morbidity is also a formidable task. Conclusions drawn from such data may be indirect. An example is the observation that asthma morbidity is highest among low-income individuals who tend to live in less desirable areas, which are frequently those with high traffic volumes and pollution.

There has been much interest in indoor environmental pollutants, such as nitrogen dioxide, sulfur dioxide, volatile organic compounds, and particulate matter, and their possible association with asthma, particularly in inner-city homes.[188,189] As with studies of outdoor pollution, difficulties in measurement over time, controlling for other exposures such as allergens, infectious agents, and social determinants of health, and linking exposures to symptoms and physical findings make research challenging.

■ Acetaminophen

It has been postulated that acetaminophen use may increase the risk of developing asthma or asthma morbidity due to its pro-oxidant effects (by depletion of the antioxidant glutathione in lung tissue).[190] Several studies have reported on the association of acetaminophen use, in pregnancy, in early life, and in adulthood, and the development of asthma.[191–195] However, the issue with studies that investigate over-the-counter medications such as acetaminophen is the possibility of confounding by indication, meaning that these individuals have comorbidities (e.g., respiratory infections) for which they may take the acetaminophen for its antipyretic or analgesic effects. A clinical trial in young children with mild persistent asthma did not show a difference in the incidence of asthma exacerbations or loss of asthma control between the as-needed acetaminophen arm versus the as-needed ibuprofen arm.[195] While this study suggests that acetaminophen intake does not affect asthma morbidity, it does not address the potential effect of acetaminophen on asthma development, and additional studies will need to be done.

NATURAL HISTORY

The natural history of asthma in early childhood can be gleaned from data from the Tucson Children's Respiratory Study.[196,197] By following a cohort of children through the first 6 years of life, study investigators characterized four groups of children: "persistent wheezers," who wheezed both before and after the age of 3 years; "transient early wheezers," who wheezed before the age of 3 years and then stopped; "transient late wheezers," who wheezed after age 3 years but not before; and "never wheezers." Fully 40% of all children wheezed in the first year of life.

Significant predictors of persistent wheezing, and hence children at greatest risk for developing chronic asthma, were young maternal age, IgE level at 9 months, parents with asthma, maternal cigarette smoke exposure in utero, abnormal lung function at birth, and male sex. It is likely that early-life wheezing is predominantly a mechanical factor and less due to severe and chronic airway inflammation. It also seems unlikely that allergen exposure predominates as a factor in early childhood.

The characteristics of older children who wheeze are atopy, female sex, and active and passive cigarette smoking. By preadolescence, atopy and environmental allergen exposure are important risk factors for wheezing in children.

In roughly half of all childhood asthmatics, symptoms decrease or disappear by late adolescence and early adulthood. Characteristics that suggest a good prognosis include male sex, precipitation of attacks by viral respiratory illness, and children with airway parenchymal dysanapsis (i.e., small airways relative to lung size). These children are predominantly male and, although often atopic, still are likely to outgrow their asthma.

In a longitudinal study of children from East Boston, initially 5 to 9 years of age followed over a 13-year period, the effect of asthma on lung growth was different for boys than girls.[198] Boys with asthma had larger growth in vital capacity than boys without asthma and tended to have mild disease. This was associated with fewer hospitalizations for asthma, despite somewhat greater prevalence than in girls. Asthmatic girls, however, had persistent reductions in FEV_1 and were more likely to be hospitalized for asthma, despite an initially reduced prevalence relative to the boys. These data are consistent with asthma being milder in boys in that boys are more likely to "outgrow" their asthma.

In contrast, the Childhood Asthma Management Program (CAMP) followed lung function of 1041 children (420 girls and 621 boys) with mild to moderate persistent asthma, who participated in a clinical trial of asthma treatment.[199] The authors used lung function data of 5415 nonasthmatic children from the Harvard Six Cities Study for comparison. In children of both sexes aged 6 to 18 years, the FEV_1/FVC ratio was significantly lower and FVC was significantly higher for asthmatic children, compared with nonasthmatic children. In contrast to the East Boston study, boys had lower FEV_1 between the ages of 10 and 18 years, whereas there were no

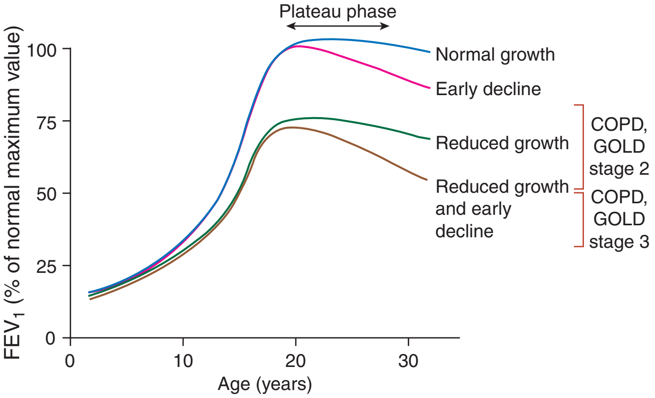

Figure 44-7 Patterns of longitudinal lung function trajectories. Normal lung growth continues after birth and reaches a peak in early adulthood. A plateau phase then ensues from the 20s to the mid-30s for most individuals. After that, gradual decline of lung function follows, mirroring physiologic aging. Perturbations of normal grown may occur, depending on environmental and other exposures over the life course of the individua. A pattern of normal growth and early decline may occur if the individual achieves normal peak lung function, but there is no plateau phase and more rapid decline starts soon after achieving peak lung function. Two other general patterns may also occur if peak lung function is not attained—that is, if reduced growth is observed. After reduced growth, a period of normal decline may ensue, or a period of early and rapid decline. These latter two patterns may increase the risk for the development of COPD later in life. *(Reproduced with permission from McGeachie MJ, Yates KP, Zhou X, et al. Patterns of growth and decline in lung function in persistent childhood asthma. N Engl J Med. 2016;374(19):1842–1852.)*

significant differences in girls. Taken together, these studies suggest that asthma that starts in early life (i.e., by age 6 years) leads to decrements in lung function that are persistent through adolescence. These patterns have been borne out in other longitudinal studies (reviewed in Grad and Morgan[200]).

In both adolescents and adults, airway responsiveness predicts the development of asthma[19,201–204] and antedates and predicts accelerated decline in lung function.[205,206] Both persistent symptoms[207] and active smoking[183] conferred more rapid rates of lung function decline in longitudinal studies. The severity of adult asthma is clearly predicted by the severity of childhood asthma, and the persistence of symptoms in childhood and early adulthood is associated with reduced lung function and more severe disease later in adult life.

The influence of childhood asthma on later adult disease continues to be elucidated by longitudinal studies. Normal patterns of lung function growth and decline have been established. In individuals with no lung disease, FEV_1 increases until early adulthood and remains stable for several years (the plateau phase). Lung function then gradually declines related to physiologic aging. Perturbations of this normal pattern give rise to increased risks for lung disease later in life (Fig. 44-7). The CAMP continuing study investigated longitudinal lung function (FEV_1) patterns among 684 children with persistent asthma.[208] About 25% of the children had a normal growth and decline pattern when compared with National Health and Nutrition Examination Survey participants who did not have asthma. The investigators categorized the rest of the children into different patterns of growth and decline: normal growth and early decline, reduced growth, and reduced growth and early decline. Each of the categories contained about 25% of the total number of children studied. At the end of the period of observation, when the mean age of participants was 26 years, 73 (11%) met spirometric criteria for chronic obstructive lung disease.

Findings from longitudinal lung function studies from CAMP and other cohorts have given rise to the idea that perturbations of lung function growth and decline can lead to increased risks for chronic obstructive pulmonary disease (COPD) or the recently recognized asthma-COPD overlap syndrome (ACO).[209] ACO is a condition that comprises clinical and biologic features of both asthma and COPD, and it applies to subgroups of patients with asthma and persistent airflow obstruction or COPD patients who have variable airflow obstruction and/or evidence of type 2 inflammation.[210,211] Because a consensus definition of ACO remains elusive, the epidemiology of ACO remains to be defined. Nevertheless, longitudinal studies of asthma in children and adults suggest that improved control might modify the risk for fixed obstructive disease later in life. For example, Sears and colleagues[212] showed that in a cohort of children followed from 9 to 26 years of age, those who had persistent wheezing consistently had lower lung function than those without persistent wheezing. Similarly, in a cohort of adult moderate to severe asthmatics with an initial mean age of 27 years and median follow-up of 11 years, participants with exacerbations had greater declines in FEV_1, such that one severe exacerbation per year was associated with a 30.2-mL greater decline per year.[213]

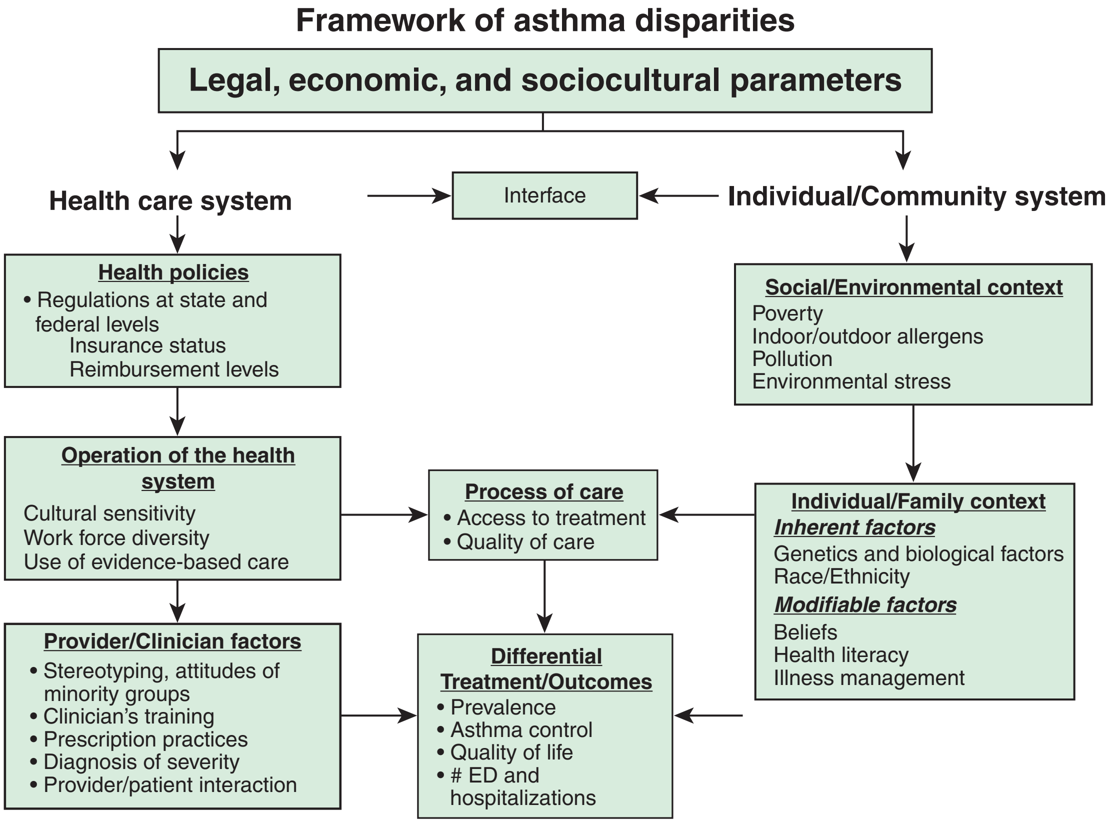
In summary, most asthma begins in childhood. Attention needs to be paid to the presence of risk factors that may lead to the development of asthma in childhood. Once asthma is established, it is imperative that efforts are focused on achieving good control of the disorder and preventing exacerbations, so as to limit the risk for developing more severe asthma, COPD, and ACO in adulthood.

HEALTH DISPARITIES IN ASTHMA

As discussed at the beginning of this chapter, asthma prevalence and especially morbidity and mortality are higher in some groups of individuals, notably including non-Hispanic black individuals, Hispanics of Puerto Rican descent, and those with lower household income. The extent to which these differences in asthma prevalence, hospitalization, and mortality are attributable to inadequate treatment and access to medical care remains unclear, but there is indisputable evidence of unequal treatment of minority and low-income groups by health professionals.[214]

Perceptions of a person's race influence social experiences, including those with the health system. In a study of women in the United States, black and Hispanic women were more likely to report a doctor's diagnosis of asthma, had higher total IgE levels, and were more likely to be sensitized to aeroallergens; however, they were less likely to report a diagnosis of hay fever or eczema.[215] These findings could represent underdiagnosis of hay fever and eczema by medical personnel, perhaps related to fewer referrals to an allergist or other specialist, or underreporting of symptoms by patients. Genetic differences alone are unlikely to explain differences in sensitization, which more likely relate to environmental exposures.

Socioeconomic factors tend to be inseparably linked to ethnicity and race for historic and political reasons. As a result, environmental factors that are the products of poverty, such as psychosocial stressors, poor dietary quality, and exposure to tobacco smoke or other pollutants or allergens, contribute to disparities in asthma prevalence and morbidity[216,217] (Fig. 44-8). A growing body of research on racial and socioeconomic disparities in asthma has focused on the effect of stress and violence in the pathogenesis of asthma and morbidity related to asthma.[218] Psychosocial stressors are associated not only with increased asthma occurrence, but also with reduced response to asthma medications such as inhaled beta-agonists.[219–221] Individuals in high-risk minority groups are frequently exposed to several asthma risk factors simultaneously, and this unequal exposure starts at conception and continues through childhood and into adulthood. For this reason, there is an



Framework of asthma disparities
Legal, economic, and sociocultural parameters
Health care system
Interface
Individual/Community system
Health policies
• Regulations at state and federal levels
Insurance status
Reimbursement levels
Social/Environmental context
Poverty
Indoor/outdoor allergens
Pollution
Environmental stress
Operation of the health system
Cultural sensitivity
Work force diversity
Use of evidence-based care
Process of care
• Access to treatment
• Quality of care
Individual/Family context
Inherent factors
Genetics and biological factors
Race/Ethnicity
Modifiable factors
Beliefs
Health literacy
Illness management
Provider/Clinician factors
• Stereotyping, attitudes of minority groups
• Clinician's training
• Prescription practices
• Diagnosis of severity
• Provider/patient interaction
Differential Treatment/Outcomes
• Prevalence
• Asthma control
• Quality of life
• # ED and hospitalizations

Figure 44-8 Multilevel model of asthma disparities. *(Reproduced with permission from Canino G, McQuaid EL, Rand CS. Addressing asthma health disparities: a multilevel challenge. J Allergy Clin Immunol. 2009;123(6):1209–1217.)*

imperative to tackle multiple environmental and social factors if the goal of reducing asthma disparities is to be achieved.

CONCLUSIONS

Although asthma prevalence, morbidity, and hospitalizations have remained stable recently, the absolute levels remain unacceptably high, particularly for certain minority groups and low-income populations. Risk factors such as obesity, prematurity, young maternal age, vitamin D deficiency, low intake of omega-3 fatty acids, and cigarette smoking are all associated with these same patient groups and speak to ongoing social and healthcare disparities. Differences in many relevant exposures are reflected by the environmental and host microbiomes, which may represent key links between exposures and asthma risk. This idea is encapsulated by the concept of "dysbiotic drift," whereby modern environmental forces drive microbial dysbiosis in a way that disproportionately impacts socioeconomically disadvantaged populations.[58] Certainly, genetic differences also exist from patient to patient. Understanding how genetic variants interact with one another and with environmental exposures to result in various asthma phenotypes will be critical to piecing together the mechanisms behind asthma prevalence and outcome disparities. With recent unprecedented computational and technologic advances in our ability to query the complex systems involved with asthma pathophysiology, we expect coming years to bring many new insights into factors that lead to distinct asthma endotypes and phenotypes and new strategies for tackling asthma disparities.

CHAPTER 45

Asthma: Clinical Presentation and Management

Omar S. Usmani
Peter J. Barnes

ASTHMA—A HETEROGENEOUS DISEASE

Asthma is a chronic inflammatory disorder of the airways characterized by marked temporal variability in airflow obstruction that is often reversible, either spontaneously or with treatment.[1] This inflammation presents clinically in susceptible patients with recurrent symptoms of wheezing, chest tightness, cough, and, occasionally, dyspnea and contributes to heightened airway hyperresponsiveness to specific and nonspecific stimuli—a pathognomonic feature of asthma. Increased airway hyperresponsiveness manifests in patients as intolerance to smoke, dust, air pollution, and strong odors, where exposure to such agents in healthy individuals does not induce such symptoms. Asthma is not a single disease entity with a unique pathogenesis, but rather recognized to be a clinical syndrome and heterogeneous disease;[2] that is, asthma comprises multiple endotypes that manifest common symptoms but have distinct and probably different pathophysiologic and etiologic mechanisms with an interplay between genetic and environmental factors. This phenotypic heterogeneity in the expression of asthma is multidimensional and includes variability in pathologic, clinical, and physiologic parameters among different patients.[3] Recent attention has directed focus on traits that are identifiable and treatable in patients with asthma, such as persistently elevated blood eosinophils, in order to achieve precision treatment with the hope of better patient outcomes.[4]

RISK FACTORS FOR ASTHMA

Several risk factors for asthma are considered below.

Atopy and Allergens

The most important factor predisposing to asthma is atopy (Table 45-1). Asthma has been classified as *atopic* (extrinsic) *or nonatopic* (intrinsic) depending on the suspected role of allergens as etiologic factors. Atopic asthma involves an exaggerated immune response characterized by immunoglobulin E (Ig-E) activation and mast cell degradation. Atopy can be clinically elicited with a positive skin prick test or specific antibodies to IgE in serum against common aeroallergens such as house dust mite, grass and tree pollens, *Aspergillus* mold, cat and dog fur, rodents (in laboratory workers), and cockroaches (in inner-city populations). House dust mite is recognized as a significant cause of asthma throughout the developed world, although the relative importance of different indoor allergens may vary among populations. Patients with atopic asthma commonly suffer from other atopic diseases, including allergic rhinitis that may be seasonal (hay fever), and may be found in over 80% of asthmatic patients; allergic conjunctivitis; and atopic dermatitis (eczema). Nonatopic asthmatic patients (approximately 10%) have a negative skin prick test, normal serum IgE concentrations, and usually show later onset of disease (adult-onset asthma). In this group, asthma is more severe and persistent, there is more sensitivity to aspirin, and commonly patients have concomitant nasal polyps. This classification, although appropriate from a pathologic perspective, does not readily help clinicians as it does not aid in establishing an etiologic diagnosis, nor does it help in defining treatment strategies.[5] There is a high prevalence of atopy among nonasthmatics and a large percentage of skin prick–sensitive persons report no allergic symptoms. About 50% of asthma can be attributed to atopy in the developed world, and the prevalence of atopy among asthmatics is determined mainly by the general prevalence of atopy in the population.[6,7] In addition, the immunopathology in bronchial biopsies and sputum in patients with nonatopic asthma appears to be identical to that found in atopic asthmatic patients. Therefore, the finding that an asthmatic is atopic does not imply that the disease is allergic in nature or that atopy is causing asthma. Moreover, respiratory tract viruses have emerged as the most frequent triggers for exacerbations in both children and adults and may play a more prominent role than allergens as triggers of acute exacerbations in most patients.[8] House dust mites are the most common indoor allergen, where particles excreted from the digestive tract contain the principal allergen *Dermatophagoides pteronyssinus*. Other main sources of inhaled indoor allergen are cat and dog fur and cockroaches (Table 45-1). Although asthmatic symptoms often improve when the allergen is removed, rigorous allergen avoidance has not shown any evidence for a reduced risk of developing asthma.

Although allergens are often triggers of acute exacerbations of asthma, allergens themselves may induce subclinical airway inflammation that may lead to enhanced airway responsiveness

TABLE 45-1 Risk Factors and Triggers Involved in Asthma

Endogenous Factors	Environmental Factors	Triggers
Atopy	Allergens—indoor	Allergens (especially house dust mite, animal dander, cockroach, indoor fungi, perennial allergens, and seasonal pollens)
Airway hyperresponsiveness	Allergens—outdoor (fungi, pollens)	Changes in the weather (cold air, thunderstorms)
Ethnicity	Obesity	Drugs (angiotensin-converting enzyme inhibitors, aspirin, β-blockers, NSAIDs)
Gender	Occupational sensitizers	Exercise and hyperventilation
Genetic predisposition	Parasitic infections	Extreme emotional expression (laughing, stress)
	Respiratory infections (early childhood, viral)	Irritants (household sprays, paint fumes)
	Socioeconomic status	Respiratory infections
	Tobacco smoking (active and passive)	Sulfur dioxide and pollutant gases
		Tobacco smoking

and greater susceptibility to the provocative effects of other triggers such as respiratory viral infections and exercise. In this regard, it is important to understand the distinction between triggers and etiologic risk factors. A trigger is any agent capable of inducing or exacerbating asthma, and whereas triggers may lead to symptoms, they do so only in susceptible persons who already possess the underlying asthmatic diathesis.

■ Viral Infections

Acute upper respiratory tract viral infections are the commonest triggers of exacerbations of asthma and most are due to rhinovirus infections. Viral infections not only give symptoms of the common cold and cause acute inflammatory rhinitis, but may also play a role in asthma development and, potentially, airway remodeling through increasing inflammation in the lower airways.[9] Asthma is recognized to be more common in children who have had croup or lower respiratory tract infections in early life, although viral infections in the absence of atopy do not appear to be risk factors for the development of asthma.[10] Other viruses commonly implicated in acute exacerbations of asthma are respiratory syncytial virus, influenza virus, and parainfluenza virus. Bacterial infection with species of *Mycoplasma* and *Chlamydia* are also associated with exacerbations of asthma, whereas other bacterial infections are not.

■ Occupational Exposure

Occupational asthma accounts for approximately 5% of all adult cases of asthma, and the disease can often be classified according to its etiology. In these circumstances, not only is the specific agent that triggers the symptoms known, but the same agent is usually the underlying cause of asthma.

■ Exercise-Induced Asthma

Many asthma patients have worsening of symptoms on or after physical exercise; another category of asthma is exercise-induced, where exercise per se is not the cause of asthma but rather one of many nonimmunologic triggers that produce symptoms in patients who already have the disease. In this condition, the trigger is thought to be the drying of the airway mucosa as a result of hyperventilation that leads to osmotically induced mast cell mediator release and bronchospasm.[11]

■ Obesity

Obesity is a major risk factor for asthma where abdominal obesity (waist circumference) and general obesity (BMI) both show a strong correlation with the risk of new-onset asthma.[12] Obese asthmatics often have excessive symptoms and are less responsive to corticosteroid therapy.[13]

■ Drugs

Drugs that may worsen asthma control include β-blockers, occasionally angiotensin-converting enzyme (ACE) inhibitors, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs).

■ Small Airways Disease

Although not a risk factor in the true sense, it is increasingly being recognized that untreated small airways inflammation disease may predispose patients to worsening asthma, and studies show that the prevalence of small airways disease is approximately 50% in the asthmatic population.[14,15]

CLINICAL PRESENTATION AND DIAGNOSIS

Asthma is a clinical diagnosis made on the basis of a medical history of typical symptoms, with consideration to provocative factors, and supported with objective confirmation of variable airflow obstruction. As the disease is heterogeneous in its presentation and severity, the clinical features of asthma show great variability both between individual asthmatics, and also within the same patient over time. It is also important to recognize that asthma is often associated with different comorbidities, including allergic rhinitis, atopic dermatitis, rhinosinusitis, gastroesophageal reflux disease, diabetes, depression, and obesity, all of which may affect the clinical expression and severity of the disease.[16] The following clinical features and laboratory assessments are important in the consideration of the diagnosis of asthma.

■ Medical History

The typical symptoms of asthma are paroxysmal wheezing, cough, breathlessness, and chest tightness, which may temporally be related to exposure to triggers or exercise. Cough may be productive of clear or yellow/green discolored sputum, where the latter may be tenacious and difficult to expectorate and reflect the underlying airway inflammation rather than a respiratory infection. Indeed, cough may be present in isolation to other symptoms and as the sole manifestation of an episode of asthma.[17] Breathlessness may occur as a result of the dynamic lung hyperinflation that accompanies acute asthma episodes, and patients may report the sensation of difficulty in “getting air in” their lungs. Exertional symptoms may not be apparent if the patient’s ability to exert themselves is limited by other health conditions such as rheumatologic or cardiac disease, and therefore asthma may be underdiagnosed in the elderly. No single symptom is specific or more significant for asthma, although wheezing is a useful sign, as nonasthmatics rarely report frequent wheezing. In younger patients, the symptom of chest tightness is helpful, since it occurs more often in association with asthma than with other pulmonary or cardiac disorders. The pattern of symptom occurrence, the precipitating or aggravating factors, and the profile of a typical exacerbation are important elements in the clinical evaluation.

In patients with poorly controlled asthma, symptoms may temporally evolve slowly over days or weeks, or present abruptly. The severity and frequency with which symptoms occur vary greatly within the asthmatic population. The recurrent paroxysmal nature of symptom presentation is characteristic of asthma, and symptoms improve, sometimes rather spontaneously, although usually with treatment. Nocturnal episodes are common in adult asthmatics, and typically patients awake in the early hours of the morning with symptoms. Distinguishing whether nocturnal symptoms are due to asthma, angina, or gastroesophageal reflux may be difficult, but early-morning asthma symptoms are usually relieved with administration of inhaled bronchodilators, in contrast to cardiovascular symptoms which occur at any time during the night, and gastroesophageal reflux which tends to cause symptoms soon after the patient reclines at night.

Chest symptoms that vary by season and are accompanied by symptoms of irritation of other mucus membranes, such as conjunctivitis and rhinitis, are typical of allergic asthma. Triggers such as indoor allergens (e.g., house dust mite, cockroach, animal dander proteins) are more likely to result in perennial symptoms, whereas pollens and some mold spores are likely to provoke seasonal symptoms. The presence of rhinosinusitis, nasal polyps, conjunctivitis, or eczema, coupled with a family history of asthma or atopy, may further support the diagnosis of asthma. Symptoms after heavy exertion, especially in the cold air, are highly suggestive of exercise-induced asthma, and patients typically experience symptoms at the end of exercise, rather than during its performance. Excessive coughing after exercise in the absence of wheeze may also be a sign of asthma. Premenopausal women with asthma may experience a deterioration of asthma control perimenstrually.[18] Indeed, compared to men, women have a higher incidence of asthma and experience more symptoms with more recourse to rescue medication.[19] The medical history should elicit risk factors for asthma (Table 45-1), and special consideration should address symptoms induced by aspirin or those associated with the patient's occupation.

Asthma and Aspirin Sensitivity

The association of asthma and sensitivity to aspirin or other NSAIDs is well established.[20] Aspirin-sensitive asthma affects approximately 1% to 5% of all asthmatics, although it is more common in patients with severe asthma (∼20%), in some ethnic groups (such as Eastern Europeans and Japanese), and in those frequently hospitalized for their asthma. This subtype of asthma is usually characterized by a tetrad of asthma, nasal polyps, chronic hypertrophic eosinophilic sinusitis, and aspirin intolerance.

Classically, perennial rhinitis is the first symptom in this syndrome, preceding the development of aspirin sensitivity, and then followed much later by nasal polyps that are usually bilateral and originate from the turbinates and the paranasal sinuses. Even in small doses, aspirin typically causes wheezing, facial flushing, rhinorrhea, and conjunctival irritation. Although aspirin-induced asthmatic episodes often resemble allergic reactions, there is no evidence that immunoglobulin (Ig)-E–related mechanisms are at work. Aspirin-induced asthma is due to blockade of cyclooxygenase 1 by nonsteroidal anti-inflammatory drugs and has been associated with enhanced leukotriene production and mast cell activation, but the cellular pathways responsible for these events remain unclear. The diagnosis of aspirin sensitivity is made on the basis of the clinical history and can be confirmed by a provocative aspirin challenge, although this test carries a potential health risk of anaphylaxis for the patient. Individuals with asthma, nasal inflammation, and recurring nasal polyps with sensitivity to aspirin have the condition known as "Samter's triad," characterized by dramatic worsening of respiratory symptoms as a reaction to taking aspirin or similar nonsteroidal anti-inflammatories.

Aspirin-sensitive asthma usually responds to standard therapy with inhaled corticosteroids (ICS), although the condition is associated with severe asthma, a condition comprising a group of patients often refractory to treatment with inhaled and oral CS. Hypothetically, antileukotriene therapy should be efficacious in these patients, but it has been found to be no more effective compared to their use in patients with allergic asthma. Aspirin desensitization may sometimes be needed and should only be performed in specialized centers. In all asthmatic patients with aspirin sensitivity, the nonselective cyclooxygenase (COX) inhibitors should be avoided, but when an anti-inflammatory analgesic is needed, the selective COX-2 inhibitors are usually safe to use.

Occupational Asthma

Occupational asthma is asthma arising de novo that is initiated as a consequence of exposure to a specific etiologic agent in patients without prior asthma. In contrast, work-exacerbated asthma is defined as the worsening of asthma, that is already pre-existing or concurrent, triggered by nonspecific irritants in the workplace.[21] Occupational asthma may be classified into: (1) that caused by a sensitizing agent in the workplace (sensitizer-induced asthma) where the specific sensitizing agent causes asthma through an identified underlying immunologic mechanism, and (2) asthma caused by exposure to irritant compounds (irritant-induced asthma) where the exposure agent is not considered to be sensitizing.[22] Table 45-2 highlights the causes of both sensitizer-induced occupational asthma and the common agents responsible for irritant-induced occupational asthma. The diagnosis of occupational asthma is based on a demonstrable link between asthma symptoms and workplace exposure, showing work-related variability in measurements of lung function made serially.[23] Classically, a typical history of asthma-like symptoms during the working week and improvement over the weekend or on vacation are elicited; symptoms may occur during exposure to the etiologic substance, or they may be delayed until the evening or night after the workday. Early detection and avoidance of occupational asthma is important because, if the patient is removed from exposure within the first 6 months of symptoms, there is usually complete recovery.

TABLE 45-2 Causes of Occupational Asthma

Sensitizing Agent-Induced Asthma	
Agent	**Workers at Risk**
Acrylate	Dental workers; adhesive handlers
Anhydrides	Workers using epoxy resin for plastics
Animal protein allergens	Veterinary workers; animal handlers
Cereals (grains)	Bakery workers; grain workers; farmers
Dyes	Textile workers
Enzymes	Pharmaceutical workers; bakery workers; laboratory workers
Formaldehyde, glutaraldehyde	Hospital and healthcare workers
Gums	Carpet makers
Isocyanates	Installers of insulation; manufacturers of plastics; rubbers and foam; spray painters
Latex	Healthcare workers; rubber workers
Persulfate	Hairdressers
Seafoods	Seafood handlers and processors
Wood dusts	Forestry workers; sawmill workers; carpenters
Common Agents Responsible for Irritant-Induced Asthma	
Acids (acetic, hydrochloric, sulfuric)	
Alkaline dust	
Ammonia	
Bleach	
Chlorine	
Cleaning agents	
Diesel exhaust	
Endotoxins	
Formalin	
Mustard	
Oxide (calcium)	
Paints (heated)	

Physical Examination

The most typical physical finding in asthma is wheezing on auscultation, which is usually caused by turbulent airflow through narrowed airways. Wheezing may be heard throughout the chest and is classically polyphonic, and present to a greater extent during expiration, although it may also be heard during inspiration. The quality and character of wheezing is not specific to asthma or to the severity of the underlying disease. There may be no abnormal physical findings when asthma is under control—yet conversely, in cases of very severe airway obstruction, breath sounds and wheezing may be absent. Examination of the upper respiratory tract may reveal clinical signs of rhinitis, sinusitis, or nasal polyps.

During an acute exacerbation of disease, physical signs of increased ventilation may be observed with the use of accessory

AL GRAWANY

muscles of respiration and chest signs of hyperinflation. A sign of severe airway obstruction is pulsus paradoxus, which is the exaggerated decrease in systolic blood pressure during inspiration by >10 mm Hg. As ventilatory effort can be diminished with respiratory muscle fatigue, pulsus paradoxus may be absent, but its absence does not preclude severe airway obstruction. Stridor is a high-pitched inspiratory sound and indicates airflow turbulence in the upper airways. In the acute setting, stridor should prompt a review of causes such as epiglottitis or foreign body. In chronic presentation, conditions such as upper airway tumors, tracheal–bronchial stenosis, vocal cord dysfunction/paralysis, and airway narrowing due to thyroid enlargement should be excluded.

■ Laboratory Investigation

The diagnosis of asthma is usually apparent from the medical history with symptoms of variable and intermittent airway obstruction, and objective measurements of lung function and spirometry support the diagnostic process. Similarly, the clinical history provides relevant information regarding the relationship between symptoms and allergen exposure, but skin prick testing and serology may be useful in identifying specific allergic triggers of asthma. Radiologic examination of the thorax, blood tests, and body plethysmography are not routinely indicated, unless there is some uncertainty in the diagnosis, where these tests may be used to exclude other conditions that may mimic asthma or complicate its clinical presentation.

■ Lung Function Tests

Peak flow meters are portable devices, readily available for patient use, that measure the peak expiratory flow (PEF). Serial readings of PEF that vary by more than 20% either spontaneously or in response to treatment are supportive of a diagnosis of asthma. Twice-daily PEF measurements, morning and evening, may also demonstrate diurnal variation, which is a typical feature of asthmatic patients.

Spirometry measures the expiratory volume and flow of air using forced maneuvers from full lung inflation, as a function of time. Simple spirometry is important for objectively demonstrating airflow obstruction, confirming the diagnosis of asthma, establishing the severity of the disease, and monitoring the response to therapy. Patients with asthma typically show a reduced forced expiratory flow in 1 second (FEV_1), reduced PEF, preserved forced vital capacity (FVC), and an FEV_1/FVC ratio of <0.7.[23] Home PEF monitoring may be of diagnostic use, confirming the diurnal variations in airflow obstruction, especially in patients who demonstrate normal spirometry during clinic visits. Spirometry also allows the assessment of the flow–volume loop, which shows a reduced maximum expiratory flow.

Bronchodilator reversibility is a measure of the magnitude of airway smooth muscle relaxation. A postbronchodilator increase in FEV_1 of >12% and 200 mL is often considered evidence of reversible airway obstruction, where measures are taken 15 min after an inhaled short-acting β_2-agonist (SABA). However, this level of increase is arbitrary and lacks sensitivity or specificity for detecting asthma. In addition, bronchodilator reversibility is diminished in well-controlled asthmatic patients, so it is not a good measure of asthma severity or response to therapy.

In some patients, bronchodilator reversibility may be demonstrated by a 2- to 4-week trial of oral corticosteroids (prednisone or prednisolone 30–40 mg daily). Bronchodilator reversibility may also occur in patients with chronic obstructive pulmonary disease (COPD).[24] Asthma and COPD are distinct diseases. Although an overlap "syndrome" of the two has been described, this term may be misleading due to the diversity of phenotypes arising from the variety of molecular, physiologic, and clinical features. Hence, the entity is better referred to as "asthma-COPD overlap" (ACO).[25–27] Asthmatic patients with features of COPD include smokers, patients with severe neutrophilic asthma, and chronic asthma with irreversible airway obstruction.

■ Body Plethysmography

Whole-body plethysmography is rarely required to establish a diagnosis of asthma in family practice, but it may help in patients where there is diagnostic uncertainty. In stable asthma, measurement of the lung volumes may reveal an increase in residual volume, which reflects airway closure at a lung volume that is higher than normal. Air trapping is typically seen in patients with severe asthma. Airway resistance is characteristically increased, and during acute episodes of disease exacerbation, functional residual capacity and total lung capacity also may be observed to be increased. Measurement of the diffusing capacity of the lung (DL_{CO}) may also differentiate patients with COPD from those with asthma. In stable asthma, DL_{CO} is usually normal, but there may be a small increase in some patients. In contrast, patients with COPD typically have a reduced DL_{CO}, which reflects alveolar septal destruction and loss of pulmonary capillary volume—characteristic features of emphysematous patients.

■ Bronchial Challenge Testing

Assessing bronchial hyperresponsiveness (BHR) is a sensitive tool that, although not routinely undertaken in clinical practice, may be helpful in diagnosing asthma, particularly when there is diagnostic uncertainty in the context of normal pulmonary function tests and unexplained chest symptoms (see Chapter 31).[28] Bronchial challenge tests assess the abnormally increased airway hyperresponsiveness observed in patients with asthma, by detecting the exaggerated response to inhaled bronchoprovocative agents. The provocation agents can be classified into two categories: direct and indirect. Direct stimuli such as histamine and methacholine, which are normally used in the clinic, act on airway smooth muscle receptors, whereas indirect stimuli act through intermediate pathways that include the release of mast cell mediators, and/or through local and central neurologic reflexes. Indirect stimuli include adenosine monophosphate (AMP), mannitol, exercise, hypertonic saline, and isocapnic hyperventilation.

Increased BHR is typically defined as the inhaled concentration of the bronchoprovocative agent that reduces FEV_1 by 20% (PC_{20}). This criterion for the test has maximal sensitivity but not maximal specificity and thus, when a diagnostic PC_{20} threshold of ≤8 mg/mL is used, pharmacologic challenges are sensitive tests with a high negative predictive value, that is, a PC_{20} >8 mg/mL excludes a diagnosis of asthma with a high degree of accuracy. Similarly, a positive result, although consistent with asthma, is not diagnostic. False-negative results can be obtained in patients who experience only intermittent symptoms and are tested when they are asymptomatic. The prevalence of abnormal responsiveness in nonatopic, nonasthmatic subjects who have no history of prior respiratory problems ranges between 5% and 10%. Knowledge of family history, personal atopy, and comorbidities clearly improves the prediction that abnormal airway responsiveness predisposes to the subsequent development of asthma.[29]

Technical factors related to the test procedure must be strictly controlled and follow standard operating procedures that include the aerosol generation, the method of inhalation (intermittent versus continuous), and the measurement and calculation of the response. Medications such as β_2-agonists, theophylline, long-acting muscarinic antagonists, and corticosteroids (CS) may influence the test and decrease airway responsiveness. Measuring BHR may have additional utility in the management of asthma. Patients whose disease is considered to be clinically controlled may still have BHR and underlying airway inflammation. Studies have shown that using BHR to guide treatment with inhaled corticosteroids (ICS) leads to additional improvement in symptoms, lung function, and airway biopsy findings compared with conventional assessment.[30]

Exercise testing of patients using cycle, treadmill, or free running challenges is occasionally undertaken to show post-exercise bronchoconstriction if there is a suggestive history of exercise-induced asthma.[31] In professional athletes, asthma may be both under- or overdiagnosed, and objective confirmation by appropriate lung function testing with bronchodilator or exercise challenge is often needed.[32] Allergen challenge is rarely utilized in the routine management of patients with asthma and should only be undertaken by a specialized center if a specific causative or occupational agent is to be identified, such as aspirin.

Blood Tests

Blood tests are usually not helpful in establishing the diagnosis of asthma. The eosinophil count in the peripheral blood may be raised in atopic conditions, and eosinophilia may support a diagnosis of asthma; however, a normal level does not rule out atopy or exclude asthma. In patients receiving CS, eosinophilic counts may be normal or low. Because of their poor sensitivity and specificity, blood eosinophil counts are not recommended in the routine monitoring of asthma severity or as a barometer of airway inflammation. Markedly high levels may be present in disorders such as tropical parasitic eosinophilia, allergic bronchopulmonary aspergillosis (ABPA), eosinophilic granulomatosis with polyangiitis (EGPA), and Loeffler's syndrome, as discussed elsewhere in this volume. In these hypereosinophilic conditions, clinical suspicion may warrant additional blood tests directed at ruling out vasculitis or ABPA, which are uncommon causes of asthma symptoms. Recently, blood eosinophil counts have been found to be useful in predicting which patients with severe asthma respond best to anti–IL-5 therapy.[33]

Total serum immunoglobulin E (IgE) may be measured in patients. Epidemiologic studies demonstrate an association between asthma and total serum IgE levels, standardized for sex and age. There is also a relationship between total serum IgE and asthma in patients with negative skin tests. Importantly, total IgE levels are used to calculate the dose of anti-IgE antibody therapy using anti-IgE monoclonal antibodies (e.g., omalizumab) in asthma treatment, as discussed below. Blood tests of specific IgE to inhaled allergens, radioallergosorbent testing (RAST), and ImmunoCAP may help identify or confirm allergy to specific allergens, such as house dust mite, cockroach, *Aspergillus* species, pollens, or animal dander.

In acute exacerbations of disease, arterial blood gases may reveal hypoxemia and the arterial Pa_{CO_2} may be reduced due to hyperventilation. With a severe exacerbation, the arterial Pa_{CO_2} may rise due to respiratory muscle fatigue and an inability to maintain the required alveolar ventilation.

Skin Tests

If the clinical history suggests specific aeroallergens are important triggers or when asthma symptoms in a patient are accompanied by other symptoms typical of allergic disease, such as conjunctivitis or rhinitis, skin prick tests may be helpful to determine whether the patient is allergic, and to investigate the role of specific allergens as a cause of asthma. Sensitivity to a particular allergen such as house dust mite, cockroach, *Aspergillus* species, or animal dander can be verified by skin tests or in vitro serum antibody studies (see above). Antihistamines and antidepressants should be avoided when undertaking testing, as these drugs can interfere with the response. Positive responses on skin prick testing may help encourage patients to undertake allergen avoidance measures or, in selected cases, may help develop immunotherapy regimens.

Chest Imaging

Chest radiography is usually unremarkable and normal in patients with mild to moderate asthma; however, in more severe disease, nonspecific findings such as hyperinflation, prominent hilar vessels, and bronchial wall thickening may be seen. In patients with an exacerbation of their symptoms, chest radiography may be useful to exclude a pneumothorax. Consolidation shadowing in the lung usually indicates pneumonia or eosinophilic infiltrates in patients with ABPA. High-resolution computed tomography (HRCT) of the chest may identify atelectasis, bronchial wall thickening, or areas of bronchiectasis in patients with severe asthma, but these changes are not diagnostic of asthma. Emphysema is absent. Multidetector computed tomography (MDCT) undertaken in inspiration and expiration provides additional information concerning the tracheobronchial tree during the entire respiratory cycle.

Exhaled Nitric Oxide

The measurement of fractional nitric oxide gas in the exhaled breath (FeNO) of patients is being utilized as a noninvasive test to assess intrapulmonary type 2 (T2) airway inflammation.[34] Portable, compact, handheld devices allow FeNO measurements to be undertaken at the bedside and in family practice.

Typically, asthmatic patients have elevated FeNO levels compared with healthy subjects; levels correlate with the number of eosinophils in sputum. ICS and oral leukotriene receptor antagonists have been shown to decrease FeNO levels. These observations suggest a possible role for FeNO as an index of asthma disease severity, as a test of treatment efficacy, and in the assessment of patient adherence with asthma therapy.

Measurements of FeNO have also been used successfully to titrate inhaled steroids without any loss of asthma control; thus, FeNO may be used as a tool in conjunction with other clinical measures to optimize asthma management as recommended by guidelines, that is, achieving disease control using the lowest doses of medications possible. Indeed, the combination of FeNO and blood eosinophil counts correlates with severe asthma exacerbations.[35]

In the research environment, FeNO can be partitioned into that arising from the central bronchial/conducting airways and that generated in peripheral alveolar regions, allowing an assessment of the site of intrapulmonary inflammation.[36,37] Patients with severe refractory asthma have shown greater alveolar NO concentrations compared to those with mild asthma. Increased FeNO may be a good predictor of which patients respond best to anti–IL-4/13 therapy, since IL-4Rα activation causes the release of NO from airway epithelial cells.[38]

Sputum Examination

The sputum differential count may be helpful. Induced sputum eosinophil counts have been used as an endpoint in clinical trials of therapeutic agents targeted at patients with eosinophilic lung diseases like asthma.[39] Research studies have shown that sputum eosinophilia predicts clinical outcomes, particularly asthma exacerbations, when CS are withdrawn. Induced sputum eosinophil counts have also been shown to guide anti-inflammatory treatment in patients with asthma in a management strategy that minimizes eosinophilic inflammation.[30] However, induced sputum remains a research tool, as it is a rather unpleasant procedure for the patient. Further studies are needed before measurement of sputum eosinophils can be widely used as a biomarker to monitor patients in clinical practice.

DIFFERENTIAL DIAGNOSIS

There are a number of conditions to consider in the differential diagnosis of asthma (Table 45-3). Usually, it is not difficult to

TABLE 45-3 Differential Diagnosis of Asthma

Upper Airway	Pulmonary	Cardiac	Other
Foreign body	Allergic bronchopulmonary aspergillosis (ABPA)	Angina	Anemia
Postnasal drip	Bronchiectasis	Left ventricular failure	Carcinoid
Upper airway obstruction	Eosinophilic granulomatosis with polyangiitis (EGPA)	Mitral valve disease	Functional
Vocal cord dysfunction	COPD		Gastroesophageal reflux
Tracheobronchomalacia	Cystic fibrosis Interstitial lung disease Lung cancer Pneumonia Pneumothorax Sarcoidosis		Hyperventilation Mastocytosis Obesity

differentiate asthma from other conditions causing wheeze and dyspnea. The degree of diagnostic accuracy is probably dependent on the age of the patient, where the diagnosis in young adults is usually not difficult since there are few other conditions that mimic asthma or confound its clinical presentation. With increasing age, cardiovascular disease and other forms of chronic lung disease are more common, and the differential diagnosis of episodic chest symptoms is broader.

Patients with upper airway obstruction can mimic severe asthma, and typically these patients present with localized wheeze and stridor of the large airways. Assessing the flow–volume loop in such patients will reveal a reduction in inspiratory flow as well as expiratory flow, and bronchoscopy can demonstrate the site of narrowing in the upper airways. Vocal cord dysfunction can be assessed using nasoendoscopy, which allows the observation of abnormalities in the movement of the vocal cords and is most helpful when adduction of the cords is detected in the presence of the patient's symptoms.[40] Persistent wheezing auscultated in a localized area of the chest wall may indicate endobronchial obstruction due to lung cancer or a foreign body. Eosinophilic pneumonias and systemic vasculitis, including EGPA and polyarteritis nodosa, may be associated with wheezing, and their systemic clinical manifestations may help in their identification.

COPD is usually easy to differentiate from asthma. The symptoms in patients with COPD are more persistent, show less variability, are progressive, and usually exhibit minimal reversibility to bronchodilator agents. As previously mentioned, the literature highlights an "overlap" in which patients with COPD have features of asthma with increased sputum eosinophils and a response to oral corticosteroids; these patients probably have both diseases concomitantly.[26] Important cardiologic causes to consider include left ventricular failure, where usually bibasilar lung crackles are present in contrast to the scattered polyphonic wheeze in asthma. Anemia should always be thought of as a cause of dyspnea, especially in elderly patients. The symptoms of gastroesophageal reflux disease (GERD) may be mistaken for those of asthma; however, it is important to recognize that GERD is common in patients with asthma and has been identified as a potential trigger for asthma symptoms.[41]

TABLE 45-4 Aims of Asthma Therapy

Control symptoms
Prevent (or minimize risk of) exacerbations
Eliminate emergency visits
Maintain lung function as close to as normal levels as possible
Decrease diurnal variation, especially nocturnal
Maintain normal levels of daily activities, including exercise
Eliminate or minimize adverse effects from medicine

TREATMENT OF ASTHMA

Treating asthmatic patients is generally straightforward; with effective and safe drugs, most asthmatics are now managed by family and primary care doctors. The successful management of asthma requires an appreciation of the heterogeneity of the disease with respect to etiology, clinical presentation, severity, natural history, and response to therapy. It is unlikely that a single management approach will work for all patients; hence, treatment should be tailored to the individual patient. It will also be recognized that symptom severity in patients varies over time with periods of remission that are interspersed with acute exacerbations; thus, the patient should be monitored regularly and treatment should be modified on an ongoing basis to meet the patient's current needs. There are several aims in the management of patients with asthma (Table 45-4), and although prominence has been placed on drug therapy, there are important patient-oriented approaches that focus on correct inhaler usage, emphasize self-management action plans, and address environmental control.

■ Inhaler Devices

Drug delivery to the lungs via the inhaled route remains the cornerstone of therapy for patients with asthma. Inhaled therapy targets drug directly to the lungs and allows a distinct therapeutic advantage over systemic therapy with the use of smaller drug doses, a more rapid onset of therapeutic action, and decreased adverse effects.[42]

There are several types of inhaler device and drug delivery systems used in clinical practice for the management of asthma; these include the pressurized metered-dose inhaler (pMDI), spacers, dry powder inhalers (DPIs), and nebulizers.[43] There are potentially more than 250 device drug combinations available, leading to confusion in prescribing among healthcare practitioners. Indeed, studies have shown that not just patients, but healthcare workers as well, are uncertain about the correct use of inhaler devices. Physicians' knowledge, in particular, remains poor and may be related to a lack of education and instruction about inhaler usage during their training.[44] It is confusing in the literature as there are 299 definitions of inhaler errors, but clearly it is recognized that a lack of knowledge and recognition with respect to the proper use and working of an inhaler might lead to worsening health outcomes for the patient.[45] It has been shown that training and counselling patients in their inhalation technique can increase their adherence to device usage, and patients may be assessed with respect to their suitability for a particular inhaler device by using portable handheld meters that assess inhalation flows.[46] Evidence-based guidelines from the American College of Chest Physicians[47] recommend the following points for consideration by healthcare practitioners when choosing an inhaler for their patient: (1) the clinical condition and disease severity; (2) availability of the inhaler device for the drug prescription; (3) the patient's ability to use the selected device correctly; (4) use of the same device type for all drugs; (5) the setting and convenience of outpatient and inpatient use; (6) the time required for drug

TABLE 45-5 Advantages and Disadvantages of Inhalation Devices

	Advantages	Disadvantages
Pressurized metered-dose inhaler (pMDI)	Compact and portable Multidose Quick treatment time Drug in sealed canister Inexpensive	High oropharyngeal deposition Difficulty in hand–mouth coordination Propellants may cause "cold Freon" effect and affect climate change Difficult to assess empty canister
Dry powder inhaler (DPI)	Compact and portable Quick treatment time Breath-actuated function removes need for coordination	Need adequate inhalation flow to disperse drug High oropharyngeal deposition Humidity can cause drug degradation Patients may be intolerant to additives, e.g., lactose
Nebulizers	Large doses of drug can be given Can be used with relaxed tidal breathing Suitable for young, old, and acutely ill patients Many drug solutions can be aerosolized	Bulky, cumbersome, and expensive Wasted drug in nebulizer reservoir Variation in aerosol output performance between models Time consuming Need for power source Regular cleaning and maintenance

administration; (7) cost and reimbursement; and (8) the inhaler preference of the patient as well as the prescriber. The advantages and disadvantages of the common inhaler device types are shown in Table 45-5.

Pressurized Metered-Dose Inhalers

The pMDIs contain the drug as a liquid suspension or solution with propellant in a sealed canister, and other formulation ingredients may be present such as ethanol, chemical preservatives, flavoring agents, and surfactant. Most inhaler therapies are now free of chlorofluorocarbon (CFC) propellants, which have been replaced by non–ozone-depleting propellants such as hydrofluorocarbons (HFCs). Upon actuation of the pMDI canister, there is quick vaporization of the propellant that provides the force to aerosolize and propel the liquid drug out of the canister at high velocity. Vaporization of the propellant also causes cooling of the drug aerosol, which can sometimes give rise to the "cold Freon effect"—a sensation experienced by some patients of cold aerosol hitting the back of their oropharynx, which can stop them from inhaling the drug and sometimes causes paradoxical bronchospasm. Some of the formulation ingredients added to pMDIs described above have been shown to cause bronchospasm, wheezing, and cough in asthmatic patients. pMDIs are compact, portable, and inexpensive devices. Recent advances in the technologic design of pMDIs include the addition of a dose counter.

Optimal clinical efficacy with a pMDI is obtained when the device is actuated at the start of a deep, slow inhalation lasting for 5 s, followed at the end of inspiration by a breath-hold pause of at least 5 s. Patients should be instructed to inhale "slowly, gently, naturally, deeply, and comfortably" and actuate the device in the first second following inhalation. Failure to inhale slowly and deeply with pMDIs is a more common mistake than the actual patient discoordination between inhalation and actuation.[48] However, the latter problem is more pertinent in elderly patients, and add-on spacer attachments, device-holding adaptors, and breath-actuated pMDIs have been developed to overcome the problem. Breath-actuated metered-dose inhalers utilize the patient's inspiratory force to trigger and activate the inhaler device, although it has been shown breath-actuated pMDIs offer no advantage over good conventional pMDI inhaler technique.[49] In contrast, "breath-coordinated" devices are different from "breath-actuated" metered-dose inhalers in that they do not depend upon the patient's inspiratory flow for actuation and help patients achieve coordination with aerosol inhalation. Although the current HFA propellants in pMDIs have the potential to impact climate change, the advent of new inhaler propellants will allow the complete life-cycle carbon footprint impact of pMDIs to be equivalent to other inhaler devices used in clinical practice.[50]

■ Spacers

Spacer devices are used with pMDIs and are designed to assist in the delivery of inhaled drug to the lungs by promoting ease of pMDI use, and reduce oropharyngeal deposition by slowing the high velocity of the emitted aerosol cloud.[51] The plastic walls of the spacer trap the large drug particles and this decreases oropharyngeal impaction, which may lead to a decrease in local unwanted side effects, particularly with CS, and also a reduction in systemic adverse effects by minimizing the amount of drug absorbed via the gastrointestinal tract. In addition, increasing the distance the aerosolized drug travels (by using the spacer as an extension attachment to the pMDI device) slows the emitted aerosol cloud and allows more evaporation of the propellant, leading to relatively smaller drug particles that have a greater potential to deposit within the lungs. Spacers include valve-holding reservoir chambers with a one-way inhalation valve in the mouthpiece only allowing airflow through the chamber when the patient inhales; simple extension devices that are non-valved add-on products that require a reasonably good amount of coordination; and reverse-flow devices with which the aerosol spray is actuated away from the patient into a collapsible reservoir chamber or bag through which outside air is entrained to provide the airflow stream for inhalation.

Spacer devices each differ in their design characteristics and should be prescribed only with the pMDI they are compatible with, as each spacer–inhaler combination has distinct aerosol output characteristics.[52] To reduce the electrostatic charge in spacers, which can significantly contribute to decreased drug available to be delivered to the lungs, spacers should be primed with the pMDI prior to use, and one-dose actuation at a time from a pMDI into the spacer device should be employed, as opposed to simultaneous multiple-dose administrations. Spacers should be washed with ionic detergent and air dried. Antistatic spacer devices are available.

Dry Powder Inhalers

DPIs are propellant-free devices that contain finely milled, powdered drug particles bound into loose aggregates, or drug particles associated with larger carrier molecules, such as lactose. DPI devices are breath-actuated and critically rely on the patient's inspiratory effort to de-aggregate the drug from its carrier particle to achieve optimal delivery and deposition within the lungs. Studies have shown that DPIs are highly dependent on the patient's inspiratory flow for therapeutic success. In addition, reported observations are that patients with asthma and those with COPD use suboptimal inspiratory flows from DPIs, leading to low pulmonary deposition.[53] In a large database study, insufficient inspiratory effort from DPIs was the most common inhaler error in this device class and was associated with significant worsening of asthma and increased frequency of disease exacerbations.[54]

DPIs can be classified into single-dose and multiple-dosing delivery systems. Single-dose systems may require drug to be individually loaded into the inhaler prior to use, or may be devices from which individual doses are dispensed from punctured gelatin capsules. In contrast, multiple-dosing delivery DPIs avoid the inconvenience associated with repeated drug loading and can be divided into "multi-dose" or "multi–unit-dose" systems. Multi-dose systems deliver drug that is metered from a powder reservoir, whereas multiple–unit-dose devices contain either drug sealed in individual foil blisters or drug sealed in pockets on a moving strip. Deterioration of the drug may occur in damp and humid conditions; hence, all these devices should be stored in a dry environment. A newer generation of DPIs rely less on the patient's inspiratory effort, requiring either lower inhalation flows to aerosolize the drug or, in some circumstances, deliver the drug wholly independent of the patient's breathing maneuver.

Nebulizers

The main types of nebulizer commonly used in clinical practice can be divided into two categories: ultrasonic and jet nebulizers.[55] Ultrasonic nebulizers utilize the vibration from a piezoelectric crystal at a high frequency to produce aerosol clouds for inhalation from the liquid drug. Ultrasonic nebulizers are smaller and less noisy compared to jet nebulizers, but are usually less robust, more expensive, and not as effective in nebulizing liquid suspensions of drug. Jet nebulizers use either compressed gas or an electrical compressor to generate aerosolized particles. High-velocity air streams are generated and directed through a narrow Venturi opening, across the liquid drug solution/suspension, to produce aerosolized droplets within the nebulizing chamber.

Nebulizers require tidal breathing at rest for effective use and do not require much patient coordination. However, there is great variation in the aerosol output generated from each of the different nebulizer devices, and the inhalation maneuver will affect drug delivery to the lungs that can be greatly reduced with crying, as may occur with children, or when there are shallow and rapid inhalations.[56] Consideration should be given to the nebulizer–facemask combination, as incorrect mask insertion into the nebulizer may give rise to unwanted deposition of drug onto the face and eyes, particularly in children. Generally, nebulizer devices are large, lack portability, and have a longer treatment time than conventional inhalers.

There is now a newer generation of nebulizer devices that offer a marked improvement in the efficiency and precision of pulmonary drug delivery.[57] These devices are more costly than conventional nebulizers, but they may be cost-effective by decreasing drug loss from the nebulizer chamber, particularly during exhalation, and by delivering a reduced drug dose more effectively. Nebulizer systems have also been developed to control the patient's inhalation maneuver so as to minimize the variability in dose delivery that occurs during use. Finally, there are systems that provide feedback to the patient and allow an assessment of patient compliance.

THERAPEUTIC DRUGS

A wide variety of agents are used in the management of asthma. Additional discussion can be found in Chapter 145.

Bronchodilators

Bronchodilators reverse the bronchoconstriction of asthma, principally by acting to relax airway smooth muscle, and this results in the rapid relief of symptoms. Bronchodilators are not adequate to control asthma in patients with persistent symptoms, as they have little effect on the underlying airway inflammation. The classes of bronchodilators in current clinical use include β_2-adrenergic agonists, anticholinergics, and phosphodiesterase inhibitors, with β_2-agonists being the most efficacious.

β_2-Adrenergic Agonists

Inhaled β_2-adrenergic agonists are the drugs of choice for relief of respiratory symptoms due to acute airway obstruction.

Mode of Action β_2-Agonists activate β_2-adrenergic receptors resulting in an increase in intracellular cyclic AMP, which leads to relaxation of airway smooth muscle cells. β_2-Agonists act as functional antagonists; that is, they prevent and reverse the contraction of airway smooth muscle cells by bronchoconstrictors, and it is this action that mainly accounts for their efficacy as bronchodilators in asthma. These drugs also have nonbronchodilator effects, including the inhibition of mast cell mediator release, inhibition of sensory nerve activation, and reduction in plasma exudation—all of which may be clinically useful.[58]

Clinical Use SABAs, such as albuterol and terbutaline, have a rapid onset of action and a 3- to 6-h duration of activity. This pharmacodynamic characteristic of a rapid onset of bronchodilation allows these drugs to be used as quick-relief medications or "relievers" on an as-needed basis. As a matter of caution, increasing use of SABA indicates that asthma is not controlled and patients should be reviewed. Indeed, the overuse of SABA has been linked to high levels of mortality from asthma.[59]

At recommended doses, inhaled β-agonists have few adverse effects, although when used at higher doses by nebulizer, patients may experience short-lived side effects. Long-acting β_2-agonists (LABAs) include formoterol and salmeterol. Both drugs are given twice daily by the inhaled route and have a duration of action of more than 12 h. In particular, formoterol has an onset of action as rapid as albuterol and can be used as a "reliever" component in fixed-dose combinations of LABA with ICS medication.[60] LABAs should not be used as monotherapy for the control of asthma of any severity and should not be given in the absence of ICS therapy, as they do not control the underlying inflammation. However, fixed-dose combinations of LABAs with ICS are now increasingly used in the management of asthma and have proved to be highly effective in improving control, reducing disease exacerbations and allowing use of lower doses of ICS.[61] Studies have also shown the clinical benefits of LABA/ICS fixed combinations compared with the monocomponents administered using two separate inhalers. The combinations of formoterol and budesonide, and formoterol and beclomethasone dipropionate, have been demonstrated to be effective when used as both a controller and reliever agents (single maintenance and reliever therapy [SMART]), thus providing the advantage of a single device used for both purposes.[62] Recent approaches in the management of mild asthma suggest the use of ICS with formoterol in combination as rescue medication instead of SABA, although this is as yet unlicensed.[63,64]

Adverse Effects The most common adverse effects of β_2-agonists are palpitations and muscle tremors, which are unusual with drug administration using the inhaled route; these adverse effects are seen more commonly with high-dose nebulizer therapy and in elderly patients.

The safety of β_2-agonists has been an issue of concern. An association has been demonstrated between the amount of SABA used and asthma deaths, but thorough analyses demonstrate that the increased use of rescue SABA implies poor asthma control, which itself is a risk factor for asthma death. A slight increase in deaths from asthma has been observed with the use of LABA, but this is most likely related to the lack of use of parallel ICS, as the LABA therapy on its own fails to suppress the asthmatic airway inflammation, highlighting the need to always use ICS when LABAs are given. This can be achieved by using a combination ICS/LABA inhaler.[65] Patients should also be reminded to avoid β-adrenergic receptor–blocking drugs, including those contained in topical ophthalmic preparations, as they can precipitate severe and sometimes life-threatening asthmatic episodes. Accordingly, β-blockers are contraindicated during acute asthma exacerbations; the risk–benefit ratio should be considered before β-blockers are used in stable patients with asthma. Some patients experience deterioration in their asthma control following inhaled β-agonist treatment. Possible mechanisms and contributory factors include paradoxical bronchospasm, increased BHR, and tolerance to the drug. With prolonged exposure to a drug, downregulation of the β-receptor may occur, limiting therapeutic efficacy (i.e., tachyphylaxis). Indeed, β-receptor mutations and gene polymorphisms have been implicated in influencing the response to inhaled β-agonists.[66]

Anticholinergics

Anticholinergic agents are another class of drugs to be considered in asthma management.

Mode of Action Muscarinic receptor antagonists, such as ipratropium bromide, induce airway smooth-muscle relaxation by blocking muscarinic receptors on airway smooth muscle, inhibiting vagally mediated cholinergic tone and preventing mucus secretion.[58]

Clinical Use In general, the anticholinergic drugs are not as efficacious in the acute relief of symptoms compared to the β_2-agonists. Anticholinergics prevent the cholinergic reflex component of bronchoconstriction, whereas in contrast, β_2-agonists inhibit all bronchoconstrictor mechanisms. Hence, anticholinergics tend only to be used as add-on bronchodilator treatment in asthmatics who remain uncontrolled on other inhaled therapy. In the treatment of acute severe asthma, high doses of anticholinergic therapy may be given by nebulizer, but they should only be given following β_2-agonist treatment, as anticholinergics do not have a fast onset of bronchodilation. A combination preparation of albuterol and ipratropium bromide is available for nebulization therapy. Tiotropium is a muscarinic antagonist that has been used in the management of patients with COPD and is currently the only long-acting muscarinic antagonist monotherapy that has been licensed for use in asthmatic patients with poorly controlled asthma in steps 4–5 (see below). Tiotropium has a higher selectivity for antagonism of M_3 receptors and dissociates from receptors more slowly, collectively leading to prolonged smooth muscle relaxation and long-acting bronchodilation.[67] The combination of a LAMA with ICS and LABA in one single inhaler (fixed-dose triple inhaler) has recently been licensed for uncontrolled asthma; the LAMA in the preparation is glycopyrrolate.[68]

Adverse Effects Adverse effects are usually not a concern with anticholinergics, as there is minimal absorption into the systemic circulation. The most commonly experienced side effect is dry mouth; in elderly patients, glaucoma and urinary retention can occur.

Phosphodiesterase Inhibitors

Aminophylline and theophylline are oral phosphodiesterase (PDE) inhibitors primarily used as an adjunct bronchodilator treatment. However, due to their narrow therapeutic index and adverse effect profile, coupled with availability of safer and more effective alternatives, PDE inhibitors are now infrequently used in patients with asthma.[69]

Mode of Action Theophylline and aminophylline inhibit PDEs in airway smooth muscle cells (predominantly PDE3), which increases intracellular cyclic AMP, leading to a bronchodilator effect. However, the doses required for bronchodilator activity commonly cause adverse effects, which are mainly a consequence of direct PDE inhibition. Theophylline has been shown to exhibit anti-inflammatory effects, which are likely to arise through different molecular pathways; for example, theophylline has been shown to stimulate a key nuclear enzyme, histone deacetylase 2, which is an important intracellular mechanism for switching off inflammatory genes that have been activated.[69]

Clinical Use Theophylline is normally administered as an oral slow-release formulation, either once or twice a day, a regimen that results in more steady plasma concentrations compared with standard theophylline tablets. In severe asthmatic patients, theophylline may be used as an add-on bronchodilator treatment. Plasma concentrations of 10 to 20 mg/L are typically needed—levels usually associated with adverse effects. In contrast, the anti-inflammatory effects of theophylline seem to occur at plasma levels below the traditional therapeutic range of 10 to 20 mg/L; at low doses, the drug is better tolerated. Low-dose theophylline has additive effects to ICS and is particularly helpful in severe asthmatic patients, in whom withdrawal of theophylline may result in clear worsening of asthma control. Intravenous aminophylline is now seldom used for the treatment of asthmatic patients, and only very rarely in those with acute severe asthma exacerbations.

Adverse Effects The adverse effects of theophylline are directly related to drug levels in plasma and are infrequently observed at concentrations below 10 mg/L. Measurement of plasma theophylline may be useful in determining and guiding the correct clinical dose. Headaches, nausea, and vomiting are the most common adverse effects, which arise from the inhibition of PDE4. Palpitations and diuresis may be troublesome, and with higher plasma concentrations, epileptic seizures, cardiac arrhythmias, and death may occur due to adenosine A_1-receptor antagonism. Oral theophylline is well absorbed through the gastrointestinal route and is largely inactivated in the liver by the enzyme CYP450. Consequently, drugs that inhibit CYP450 activity, such as allopurinol and erythromycin, may increase plasma levels of theophylline causing a greater potential for adverse effects.

PDE4 inhibitors increase cyclic AMP in inflammatory cells and have anti-inflammatory effects. Although the PDE4 inhibitor roflumilast is approved as an additional therapy in severe COPD patients, there have been few studies in asthma. Its use is limited by frequent side effects (diarrhea, nausea, headaches) at therapeutic doses.

■ Corticosteroids

Corticosteroids (CS) are potent anti-inflammatory agents. When administered by the inhaled route, CS are the most effective therapy available for treating and controlling asthma and have greatly contributed to a reduction in asthma mortality in the Western world.[70]

Mode of Action

CS reduce the number of inflammatory cells, as well as their activation, in the airways. The reduction in eosinophils, activated T lymphocytes, and surface mast cells contributes to the decrease in airway hyperresponsiveness that is seen with CS therapy.

Several molecular mechanisms underlie the action of CS on airway inflammation. The main pathways center on the inhibition of transcription factors NF-κB and AP-1, which switch off transcription of multiple activated genes encoding inflammatory proteins, such as cytokines, chemokines, inflammatory enzymes, and adhesion molecules.[71] Another key mechanism in the action of CS is the inhibition of the recruitment of histone deacetylase 2 to the inflammatory gene complex, which reverses the histone acetylation associated with increased gene transcription. CS increase the expression of β_2-receptors, which may contribute to the complementary clinical effects observed when CS are combined with LABA.[72] Transcriptional activation is responsible for most of the endocrine and metabolic adverse effects of CS.

Clinical Use—Inhaled Corticosteroids

CS are usually administered by the inhaled route for maintenance controller therapy in patients with asthma. ICS have been shown to prevent the symptoms of asthma, reduce severe exacerbations rates, improve lung function, and reduce airway hyperresponsiveness. Early and timely treatment with ICS appears to avert the irreversible changes in airway function that occur with chronic asthma. Patients with persistent asthma stabilized on ICS experience increased exacerbations when treatment is withdrawn, indicating that ICS suppress symptoms and inflammation but do not cure the underlying disease.

ICS are beneficial in treating asthmatic patients of any age and at any stage of disease severity. They are first-line therapy for patients with persistent asthma and are usually administered twice a day, although ICS may be effective given once a day in some patients with mild symptoms. The dose–response curve of ICS is relatively flat, meaning that higher doses are only incrementally better than low-to-medium doses. If low-to-medium doses of ICS do not control persistent asthma symptoms, it is usual practice now to add a LABA, preferably as a combination of the two drugs delivered from a single inhaler device.

Clinical Use—Systemic Corticosteroids

Oral CS are reserved to treat acute exacerbations of asthma. Typically prednisolone or prednisone, 30 to 45 mg, is given once daily for 5 to 10 days. Upon completion of the course of treatment, no tapering of the dose is required. A few asthmatic patients (approximately 1%) with severe disease may require maintenance treatment with oral CS; in these patients, it is important to determine the lowest dose necessary to maintain asthma control in light of the greater potential for adverse effects with higher doses. CS may also be administered intravenously (methylprednisolone or hydrocortisone) for the treatment of acute severe asthma, although studies have shown that oral CS are as equally efficacious and easier to take. The use of biologic therapies, such as anti-IgE and anti–IL-5, reduces the requirement for oral CS in selected patients with very severe asthma. All patients on maintenance oral CS should be considered for these therapies.

Adverse Effects

ICS may give rise to local oropharyngeal adverse effects, such as oral candidiasis, dysphonia, and hoarseness, but these may be lessened with the use of a spacer device. Concerns exist about the systemic adverse effects of ICS from swallowing of the oropharyngeal dose and lung absorption, but these effects depend upon the individual pharmacokinetic properties of the different CS. Overall, studies show that ICS have minimal systemic adverse effects.[73] At higher drug doses, ICS may suppress plasma and urinary cortisol levels, and in prepubertal children the initial decrease in attained height from use of ICS persists as a reduction in adult height; however, it is not progressive or cumulative and represents a loss in height of approximately 1 cm. Most importantly, ICS allow the effective control of asthma symptoms and disease, and maintenance therapy may decrease the need and number of prescribed courses of oral CS, thereby reducing the total systemic exposure to CS.

Oral CS give rise to greater systemic adverse effects than ICS, with a greater potential in those on chronic maintenance therapy. Adverse effects include bruising, diabetes, truncal obesity, osteoporosis, duodenal and gastric ulceration, hypertension, mood and behavioral changes, proximal myopathy, and cataracts. It is important to assess and monitor bone density if patients are administered chronic oral CS therapy so that preventive treatment for osteoporosis with bisphosphonates, or estrogen in postmenopausal women, may be initiated if levels of bone density are borderline or low. If CS adverse effects are a considerable problem, steroid-sparing agents may occasionally be considered.

■ Antileukotrienes

Leukotriene pathway inhibitors are a group of compounds that alter the pathophysiologic effects of leukotrienes derived from the 5-lipoxygenation of arachidonic acid. Two classes of agents are available: inhibitors of the 5-lipoxygenase enzyme (e.g., zileuton) and cysteinyl-leukotriene receptor type 1 antagonists (e.g., montelukast, zafirlukast, pranlukast).[74]

Mode of Action

Cysteinyl-leukotriene receptor type 1 antagonists inhibit the smooth muscle bronchoconstriction, microvascular leakage, and eosinophilic airway inflammation that occur through activation of cysLT_1 receptors. These agents act predominantly on the inflammatory mediators produced by mast cells in asthma and also, to a lesser extent, on mediators produced by eosinophils.

Clinical Use

Antileukotrienes have less effect on airway inflammation and provide modest clinical benefit compared to ICS. ICS are more effective anti-inflammatory agents and are clinically superior to antileukotrienes in controlling asthma. Antileukotriene treatments may be useful as add-on therapy in selected patients with mild asthma on low-dose ICS, although these agents are less efficacious than add-on therapy with LABA. Antileukotrienes may be helpful when CS use is poorly tolerated or not desired by the patient, or if there is concomitant rhinosinusitis. These drugs are usually given orally once or twice a day.

Adverse Effects

Antileukotrienes are usually well tolerated, but they can sometimes give rise to gastrointestinal upset, hepatotoxicity, and hypersensitivity reactions, including anaphylaxis and angioedema.

■ Cromones

Cromolyn sodium and nedocromil sodium are classified as asthma-controller drugs. Their main mechanisms of action seem to be to inhibit sensory nerve and mast cell activation; therefore, they are effective in blocking trigger-induced asthma, such as allergen- or exercise-induced symptoms. However, these drugs have a short duration of action, requiring inhalation up to four times a day, and consequently have relatively little benefit in the long-term control of asthma. They were popular in the treatment of children with asthma because they are remarkably safe, although they are inferior to ICS with respect to all relevant clinical outcomes and are no longer recommended in guidelines. Low-dose ICS are now favored in children, as they are more efficacious and have an established safety profile.

■ Corticosteroid-Sparing Treatments

Some patients experience serious adverse effects with CS therapy, especially oral CS therapy in those with severe asthma. In an attempt to minimize CS exposure and reduce patient requirement, various immunomodulatory treatments have been tried. Steroid-sparing therapies include azathioprine, colchicine, cyclosporin A, gold, methotrexate, and intravenous gamma globulin; however, none of these treatments have shown long-term efficacy and, importantly, each has been associated with a high-risk adverse effect profile. They cannot be recommended in lieu of CS.

Anti-IgE Monoclonal Antibodies

Omalizumab is a monoclonal antibody to IgE that inhibits IgE-mediated reactions by neutralizing serum IgE without binding to cell-bound IgE. It is used as an adjunctive agent for atopic asthmatic patients who are dependent on CS therapy.[75] Studies in patients with moderate to severe CS-dependent asthma show an improvement in asthma control, a reduction in the number of disease exacerbations, and a significant steroid-sparing effect. However, anti-IgE treatment is very expensive. Its use is appropriate only for specific patients who have a high circulating IgE within a precise range and whose asthma is not controlled on maximal doses of inhaled or oral CS therapy. Omalizumab is usually given as a subcutaneous injection every 2 to 4 weeks. Although relatively safe with few significant adverse effects, anaphylaxis has occasionally been reported. As there are no good predictors of clinical response, a 3- to 4-month trial of therapy should be undertaken to ascertain any objective benefit with this treatment.

Anticytokine Therapy

Despite maximal inhaled therapy and maintenance courses of OCS treatment, a small proportion of patients with asthma are extremely difficult to control and may be candidates for biologic treatment of their disease. A number of immune system modulators have recently been licensed and approved for use in patients with severe asthma. Of these, the main biological therapies are inhibitors that target key cytokines involved in the chronic airways inflammation of asthma.[76]

Inflammation in patients with asthma is usually allergic, with activation of mast cells and of eosinophils mainly orchestrated by type 2 immunity, which involves T helper 2 (Th2) cells and type 2 innate lymphoid (ILC2) cells, IL-4, IL-5, and IL-13. These key cytokines have been targeted for therapeutic purposes.[76]

Anti–IL-5 Treatments

Currently, three anti–IL-5 treatments have been approved for use in selected patients with severe type 2 asthma: mepolizumab, reslizumab, and benralizumab.[77]

Mepolizumab is a blocking antibody to IL-5 administered by subcutaneous injection every 4 weeks. Initial studies in unselected patients and those with milder disease were unconvincing in demonstrating a benefit to patients. However, recent clinical trials in severe asthma patients using specific inclusion criteria, including ongoing respiratory symptoms, frequent disease exacerbations, and increased sputum eosinophils (>3%), showed a reduction in both disease exacerbations and the maintenance dose of OCS.[78] However, there was only little improvement in respiratory symptoms, pulmonary function, and quality of life; hence, ongoing inhaled maintenance therapy with ICS/LABA may still be needed.

Reslizumab is another blocking antibody to IL-5 administered intravenously every 4 weeks (a potential drawback compared to other treatments) that has shown similar benefit to mepolizumab. Once again, the clinical effectiveness is dependent on eosinophil counts (blood eosinophils ≥400/μL).[79] Higher doses of reslizumab than mepolizumab can be administered, so it may be considered in those patients who do not show a good response to mepolizumab.

Benralizumab is an antibody to IL-5 receptor α (IL-5Rα) administered subcutaneously every 4 to 8 weeks; it has been shown to benefit not only patients with severe asthma, but also those with milder disease.[80] In a study of patients presenting with an acute asthma attack, benralizumab administered as a single dose led to decreased disease exacerbations in the following 12 weeks post-exacerbation, particularly in those patients who were hospitalized because of their acute exacerbation.[81] Benralizumab induces death (apoptosis) of eosinophils, thereby rapidly clearing eosinophils in the airways. It may have a more rapid onset of action than antibodies targeting the cytokine. Increased blood eosinophil counts predict a better response; therefore, only patients with blood eosinophil counts greater than 300/μL should be considered for this therapy.

Anti–IL-4, Anti–IL-13 Treatments

IL-4 and IL-13 signal through a common receptor, IL-4Rα, and both cytokines promote eosinophilic airways inflammation. In adult patients with asthma, IL-4 expression is low, and poor outcomes in preliminary clinical studies directed attention to blocking IL-13 directly.[76] However, lebrikizumab, an antibody specifically blocking IL-13, showed marginal benefit in two recent clinical trials and has not been pursued for clinical approval.[82] Similarly, tralokinumab, also an IL-13 blocking antibody, performed poorly in recent clinical trials and was associated with minor changes in lung function, asthma control, and exacerbation outcome measures in patients with severe uncontrolled asthma.[83] In contrast, clinical trials with dupilumab, an antibody against IL-4Rα, have shown much better clinical benefit than those using IL-13 antibodies. Dupilumab, administered subcutaneously every 4 weeks, has been shown to improve symptoms and lung function and to markedly reduce asthma exacerbations in moderate to severe asthma poorly controlled on maximal inhalation treatments. Interestingly, in these patients FeNO was a good biomarker of response, but baseline blood eosinophil counts were not.[84] The drug is also licensed for use in patients with severe eczema and is effective in the treatment of rhinosinusitis and severe nasal polyposis.

Anti-TSLP Treatment

Blocking upstream cytokines, such as thymic stromal lymphopoietin (TSLP), that orchestrate type 2 inflammation may be more effective than targeting individual downstream cytokines. Tezepelumab, a blocking antibody to TSLP, has been shown to be effective in inhibiting responses to inhaled allergen (early and late) and in reducing blood and sputum eosinophils, FeNO, and IgE in patients with mild asthma.[85] In patients with severe asthma, clear reductions in acute disease exacerbations and decreases in FeNO and blood eosinophil counts have been observed.[86] Tezepelumab is also effective in patients with low or normal blood eosinophils, as it may also target T cells (Th1, Th17, ILC1, ILC3) that orchestrate neutrophilic inflammation.

Other Immunomodulating Treatments

Currently, many drugs are in development or in early human clinical trials in patients with subtypes of severe asthma that target various aspects of the inflammatory pathways, including those directed at cytokines (IL-25, Il-33, GM-CSF, IL-1, IL-6), transcription factors (GATA-3), neutrophils (TNF, IL-17), or chemokines (CCR3, CXCR).[76] Anti–TNF-α antibodies, although mechanistically promising, have not been shown to be effective in patients with severe asthma. New, broad-spectrum anti-inflammatory treatments include phosphodiesterase 4, NF-κB, and p38 MAP kinase inhibitors; these drugs act on signal transduction pathways that are common to many immune cells and present the risk of troublesome adverse effects, particularly when administered parenterally. Research is ongoing regarding potential delivery by the inhaled route.

Clear from clinical trials of biologics and the current interest in, and development of, drugs targeting the immune pathways in asthma, is that appropriate patient selection, identification of responders, and development of biomarkers to monitor response are critical in order to guide clinicians when considering use of these very expensive treatments. The effectiveness of anti–IL-5 treatments is highly dependent on the baseline blood eosinophil count; greater clinical response is seen in patients with severe asthma with a blood eosinophil count ≥300/μL. In contrast, FeNO, rather than blood eosinophils, is a good predictor of response to anti–IL-4/13 treatments. For anti-TSLP treatment, effectiveness does not depend on raised blood eosinophil counts or FeNO.

It has also been recognized that existing specialist clinic resources must be directed at addressing nonadherence to inhaled therapy, as biologic interventions could end up becoming a very costly and expensive alternative to rectify nonadherence.[87] Most studies have been short-term (12 months). The long-term safety profile of these agents, particularly on the body's immune defense system against infections, is largely unknown. However, as licensed treatments are now being used, these data will be gathered during postmarketing surveillance.

■ Immunotherapy

Allergen-specific immunotherapy (ASIT) involves the repeated administration of allergen products to induce immunologic and clinical tolerance to the specific allergen. ASIT may be given subcutaneously.

Allergen immunotherapy is of benefit in highly selected patients with defined allergic triggers.[88] Asthmatic patients with a single specific allergic trigger and concomitant nasal symptoms derive the greatest benefit compared with patients with multiple allergic triggers. Allergen-specific studies have supported efficacy of this route of administration. There is a risk of adverse effects, including anaphylaxis. In contrast, sublingual ASIT has recently been shown to be an effective and safe alternative in patients with seasonal allergy. Clinical studies with house dust mite allergic asthma are underway.

NONPHARMACOLOGIC MANAGEMENT

Alternative therapies, which may be popular and more acceptable with some patients, include acupuncture, breathing control, chiropractic, homeopathy, hypnotherapy, and yoga. Placebo-controlled studies show these treatments lack efficacy; they should not be clinically recommended.[89] The concern with these therapies is that they may lead to discontinuation of effective drug therapy and destabilize asthma control. However, as these therapies are considered not to be harmful, patients may utilize them as an adjunct to their conventional pharmacotherapy.

■ Bronchial Thermoplasty

Bronchial thermoplasty (BT) is an endobronchial intervention for the treatment of adult patients with severe persistent asthma who remain uncontrolled with ICS and LABA. BT delivers controlled radiofrequency energy to heat the airway walls and reduces airway smooth muscle mass.

Three randomized controlled clinical trials of BT versus usual care or sham intervention in patients with severe asthma have supported its effectiveness and safety: the Asthma Intervention Research (AIR) trial[90] and the Research in Severe Asthma (RISA) trial,[91] both of which both compared BT to usual care, and the AIR2 trial,[92] which compared BT with sham intervention. The AIR2 trial observed a significant reduction in severe exacerbations of asthma, decreased emergency room visits, improved asthma quality of life questionnaire (AQLQ) scores, and fewer hospitalizations. These improvements persisted through 5 years of follow-up.[93]

Patients in the trials undergoing BT did report a transient increase in symptoms related to their asthma and, during the treatment phase, an increase in hospital admissions. An interim analysis of the 3-year follow-up results of BT in a postmarketing surveillance study mandated by the FDA (PAS2, Post-FDA Approval Clinical Trial Evaluating Bronchial Thermoplasty in Severe Persistent Asthma), confirmed findings observed from the AIR2 follow-up, with significant decreases in the percentage of patients with severe exacerbations (45%), emergency department visits (55%), and hospitalizations (40%).[94]

FUTURE TREATMENTS

Although current asthma therapy with CS and β_2-agonists is effective in controlling disease symptoms in the majority of patients, poorly controlled asthma still remains a problem in a considerable proportion of patients.[95] Poor adherence to prescribed controller therapy contributes to poor asthma control, and the use of combination LABA/ICS therapy delivered by a single inhaler device, or the use of combination LABA/ICS therapy as both a controller and reliever agent, may partly address this problem. LAMA have been used as add-on therapy in worsening asthma.[67] Recently, the combination of a LAMA (glycopyrronium) with ICS and LABA in one single inhaler (triple inhaler) has been licensed for uncontrolled asthma.[68]

In everyday practice, the vast majority of inhaler devices target treatment at the large airways. However, it is becoming increasingly recognized that it is important to target inhaled therapy to the peripheral lung regions in order to treat ongoing inflammation that may additionally be contributing to the patient's unstable clinical state.[96] Asthma continues to remain an unmet need, as the lifelong treatments currently used only address the clinical symptoms and have little effect on the underlying structural alterations associated with asthma. A pressing need exists for development of novel therapies for patients who have side effects from systemic CS.[97]

CS resistance is a particular problem in patients with severe asthma. Several molecular mechanisms have been elucidated that may lead to novel therapeutic approaches, including the reversal of this resistance by drugs such as theophylline and nortriptyline. Studies of the steroid-sparing effects of macrolide antibiotics in asthma management have yielded discordant results. Macrolides might benefit some patients with infection by atypical bacteria, but recent results are not encouraging; there may be an effect in patients with predominant neutrophilic asthma.

MANAGEMENT OF CHRONIC ASTHMA

Global directives in asthma now focus on the control of asthma symptoms using a stepwise approach to drug therapy.[1] There has been a shift away from treatment based on disease severity with the realization that asthma does not necessarily remain in the same clinical category indefinitely; it may change over months or years, and patients may move up or down in their asthma severity based on a variety of factors, such as the presence of allergens, correct or incorrect use of medications and treatments, and lack of adherence to the prescribed treatment regimen. If control at a particular step is not adequate, then treatment should be increased to the next level. Principles of therapy embody the fact that effective treatment should lead to better asthma control and allow the patient to move to a less severe category; therefore for ongoing management of asthma, classification by level of control may be more relevant and useful than disease severity. The aims of chronic therapy in asthma are highlighted in Table 45-4.

The Global Initiative for Asthma (GINA) stratifies patients into four categories of asthma control level: (1) controlled (therapy is maintained or stepped down), (2) partly controlled (consideration is given to stepping up therapy), (3) uncontrolled (treatment is stepped up until symptom control is achieved), and (4) exacerbation (patients are treated according to the exacerbation algorithms).[1]

Factors determining the level of control involve an assessment of the following: daytime symptoms experienced in the last week, limitations in activities of daily living, nocturnal symptoms or awakenings, need for rescue reliever medication during the week, lung function, and number of exacerbations (if any) in the last week and last year.

■ Stepwise Treatment

The stepwise approach to asthma management incorporates a description of the levels of treatment required to achieve good asthma control.[1] Some patients may experience acute worsening of asthma control, such as those with a concomitant upper respiratory tract infection, and may need to step up more than one step at a time.

Step 1

For all asthma patients, a SABA delivered by a metered-dose inhaler gives relief of acute symptoms. Updates to global strategy documents for the management of asthma and some national country guidelines now incorporate ICS treatment at step 1, recognizing the nature of asthma as chronic inflammatory disease and the need to control (and treat worsening) symptoms with ICS maintenance therapy.[98] The increasing use of a short-acting reliever medication more than three times a week, or triggering of symptoms from exercise, provide indications that controller therapy is needed. Recent studies in the management of mild asthma suggest the use of an ICS with formoterol in combination as a rescue medication, instead of a SABA; however, this approach is as yet unlicensed.[63,64]

An important, but often overlooked, part of asthma management relates to measures to control environmental triggers. Recognized triggers that worsen asthma control, such as aeroallergens or occupational agents, should be avoided, although this is not always possible. Patients with asthma may also have several triggers; therefore, the impact of avoiding a single trigger will vary considerably between patients. However, complete removal from exposure to house dust mite has been shown to reduce asthma severity and airway hyperresponsiveness.

Guidelines recommend that influenza vaccination should be administered in adult asthmatics. However, while studies suggest it is unlikely to induce asthma exacerbations, there is no conclusive evidence regarding the efficacy of vaccination on influenza-related asthma complications or on frequency of exacerbations. Asthmatic patients, especially the elderly or those with comorbid conditions that increase the risk of death from influenza infection, should receive inactivated influenza vaccine if there are no other contraindications. The CDC recommends a single dose of Pneumovax for adults from 19 to 64 who have chronic illnesses, including asthma.

Steps 2–3

When patient symptoms are no longer intermittent, addition of a daily long-term controller medication on a scheduled daily basis is recommended. The treatment of choice for all patients is an ICS to alleviate the underlying airway inflammation. It is usual to start with a low-to-intermediate dose of ICS twice daily (e.g., 200 μg beclomethasone dipropionate [BDP] or equivalent BID), and if symptoms are controlled after 3 months the dose should be stepped down. An alternative option is to prescribe as-needed low-dose ICS/formoterol. However, if symptoms persist and are not controlled, a LABA should be added as a fixed combination drug, with an ICS delivered from a single inhaler device, as studies show a clinical advantage compared with the monocomponents administered using two separate inhalers. Indeed, low-dose ICS in combination with LABA therapy shows complementary molecular action and has been shown to be as efficacious at high-dose ICS treatment.[99] The dose of the ICS should be adjusted up or down based on the need for rescue inhaler use and patient symptoms. Alternative add-on therapies to ICS that can be considered include an antileukotriene or low-dose ICS whenever a SABA is taken; however, these are less effective than the ICS/LABA combination.

Steps 4–5

In patients with worsening symptoms, addition of a long-acting muscarinic antagonist or a leukotriene antagonist to medium-dose LABA/ICS may be helpful. The addition of the inhaled long-acting anticholinergic tiotropium bromide to LABA/ICS treatment in patients with poorly controlled asthma significantly decreases asthma exacerbations and improves lung function.[100,101] For those whose disease remains uncontrolled, stepping up with high-dose ICS/LABA is a follow-on option.

In patients with severe asthma who fail to achieve symptom control, maintenance therapy with a systemic oral CS may be indicated; however, in view of the side-effect profile of oral CS, the clinician should always aim to titrate to the lowest possible daily (or every other day) dose that maintains asthma control.

Anti-IgE therapy with omalizumab may be tried in patients with severe allergic asthma, especially those who are CS-dependent and continue to remain uncontrolled. However, this treatment is only suitable for highly selected patients.

Anti-eosinophil biologic therapies may be considered for patients with uncontrolled severe asthma with increased blood eosinophils; benralizumab is given every 8 weeks, whereas mepolizumab and reslizumab are given by monthly injection. For asthmatics who have severe asthma with increased FeNO, dupilumab is preferred, especially in patients with concomitant nasal polyposis, rhinosinusitis, and atopic dermatitis. Allergen-specific immunotherapy may be considered in this group; however, the risk of severe events, including death, is highest in patients with severe asthma. Biologic therapy is also now indicated in a small proportion of patients.

■ Step-Down Treatment

Once symptoms of asthma are stable and the patient demonstrates stable peak flow readings, the clinician should slowly decrease therapy to find the optimal dose to control symptoms. Indeed, asthma severity may fluctuate and improve with time, owing to improved disease management, changes in environmental exposure, or the natural history of the disease. Most asthma guidelines recommend a step-down approach once patients are controlled.[1]

Overtreatment of patients, particularly with ICS, can cause significant morbidity and adverse effects, especially in moderate to severe asthmatics. Such treatment may also be unnecessarily costly. Unfortunately, in such patients there is a tendency to maintain a static treatment regimen, even after symptoms are controlled and clinical stability achieved. Studies have now supported the notion that stable asthmatic patients on high-dose ICS may be overtreated, and that reductions in the inhaled dose can be achieved without significant increases in asthma exacerbations, physician visits, or recourse to oral CS use.[102] Indeed, recent studies show that an efficient inhaler device may achieve a successful step-down without worsening symptoms, disease exacerbations, or hospitalizations.[103]

A gradual reduction in medications, starting with the treatment with the greatest toxicity, should be attempted once stability is achieved and sustained for several months. Symptoms should be monitored on a long-term basis using both objective lung function and subjective symptom measures. Most patients should be maintained on an ICS, and this treatment should not be stopped since it provides anti-inflammatory protection. For asthmatic patients who needed admission to hospital or ventilatory support, a longer period of stability on maintenance therapy may be justified before consideration of a step-down treatment approach.

MANAGEMENT OF REFRACTORY ASTHMA

Most asthmatic patients are controlled with appropriate stepwise therapy, but approximately 5% are difficult to control, do not remain symptom-free despite maximal inhaled therapy, and may require maintenance treatment with oral CS. In this group of patients, a thorough investigation of factors aggravating or contributing to poor asthma control should be undertaken. It is important to check adherence with medication and inhaler technique, particularly if the patient's disease is unstable, despite the maximal recommended dose of therapy. Nonadherence with medication remains an important factor for the poor control of asthma and may be particularly manifest with ICS, as patients may be concerned about adverse effects or describe lack of immediate clinical benefit from this treatment.[87]

Monitoring adherence to ICS therapy in the clinic is difficult, as there are no useful plasma measurements that can be made. However, in contrast, measurement of plasma cortisol suppression and absolute plasma drug concentrations may be useful in monitoring adherence to oral CS. Evidence suggests nonadherence may be more common in those with psychosocial problems or depression; these conditions should be actively sought and addressed during the clinical assessment.

A detailed review of factors, such as exposure to environmental allergens, unidentified occupational agents, or drugs that worsen asthma control, including aspirin or β-blockers, also should be undertaken.

Asthma may coexist with a number of disorders that can affect lung function, and the successful management of asthma often requires treatment of these associated conditions that are thought to aggravate asthmatic symptoms. Rhinosinusitis and gastroesophageal reflux disease are the most common of the disorders associated with poorly controlled asthma. The relationship between rhinosinusitis and asthma is well established as described in the "united airway disease hypothesis," according to which treating the inflammation of allergic rhinitis in the upper airways translates into improved asthma control.[104,105]

It has also been postulated that poor asthma control may arise as a result of the inability of current inhaler devices to target drug therapy to ongoing inflammation in peripheral lung regions. Conceivably, treatment of this lung compartment with targeted anti-inflammatory therapy may result in improved symptoms.[96] In spite of the lack of data from meta-analyses that fail to show a consistent effect of antireflux therapy on asthma symptoms and lung function, many clinicians assess and treat the possibility that gastroesophageal reflux disease may be aggravating asthma.[106]

As discussed earlier, patients with vocal cord dysfunction may present with wheeze and stridor and the need for an escalation in asthma therapy. Vocal cord dysfunction can be assessed using nasoendoscopy to observe abnormalities in the movement of the vocal cords; if the diagnosis is confirmed, patients should be weaned off CS. Speech therapy intervention may be helpful. Bronchoscopy or MDCT to exclude tracheobronchomalacia may be considered. A reconsideration of the potential differential diagnoses should be explored in the refractory asthmatic patient (Table 45-3).

Patients who require high doses of oral CS to maintain asthma control are referred to as "CS-dependent" asthmatics. In contrast, patients with complete "CS-resistant" asthma show a failure to respond to high-dose oral CS therapy. However, this is very uncommon, affecting less than 1 in 1000 patients. Several molecular mechanisms have been implicated in CS resistance and the impaired anti-inflammatory action, leading to the identification of new drug targets for future therapies.[107]

Evidence has shown that in asthmatic patients who smoke (approximately 20% of the population), smoking itself hinders the anti-inflammatory action of CS, leading to relative CS resistance and the need for higher drug doses to achieve asthma control. It is recognized that compared with nonsmoking asthmatics, smoking asthmatics have a faster decline in lung function, more severe asthma, more frequent hospital admissions, and a higher risk of death. Smoking cessation should be strongly pursued in this group, as this intervention has been shown to reduce CS resistance and improve lung function.

Some asthmatic patients have unstable disease, characterized by rapid variations in lung function that may lead to recurrent and severe attacks of asthma, despite appropriate treatment.[108] These patients may be divided into two categories: (1) type I brittle asthma, characterized by a sustained pattern of chaotic peak flow variability on a daily basis; and (2) type II brittle asthma, in which asthma symptoms and lung function are well controlled, but where abrupt and unpredictable falls in peak flow may be catastrophic and result in sudden death. These patients are difficult to treat, as they do not usually respond to maximal high-dose CS therapy and may rely on subcutaneous epinephrine injections. Assessment of treatment adherence and education on allergen avoidance are particularly important in these patients, who should wear an identification bracelet noting their condition. The importance of carrying a portable epinephrine autoinjector at all times and being taught to self-administer this treatment should be a central part of their management.

ASTHMA EDUCATION AND MONITORING

Asthma education and training are important, as patients need to understand the disease, its management, proper use of inhalers, adverse effects of treatment, and, importantly, timing of use of reliever and controller treatments. Education may improve adherence to treatment recommendations and engage the patient in self-management strategies, particularly in terms of symptom recognition, identification and avoidance of asthma triggers, objective measurement of deterioration in asthma control, and treatment of exacerbations of asthma in their earliest stages by stepping up therapy. Educating the patient in the self-administration of oral CS and access to healthcare advice are also important elements in a management program, which are designed to reduce emergency hospitalizations and patient morbidity.

Studies have shown that written personal patient action plans result in better asthma control, reduced emergency department visits and hospitalizations, and decreased morbidity, in both adults and children. Written plans are particularly useful and recommended in patients with unstable disease who have frequent exacerbations. The additional provision of a program of educational sessions (one-to-one or in small groups) with a knowledgeable healthcare professional has been shown to be more effective than provision of written materials alone. Like drug therapy, the educational program and the method and frequency of reinforcement should be tailored to the patient's individual needs. Patients should be reassured that with proper treatment, symptoms and occasional exacerbations can be minimized and, in most cases, a normal lifestyle and life expectancy can be anticipated.

Home monitoring of asthma symptoms and control is an important aspect of self-management programs. PEF measurements allow patients to be monitored on a long-term basis using simple, handheld, compact portable devices. Asthma treatment guidelines recommend patients use PEF measurements not only to monitor the course of the disease, but also to dictate self-administered treatment regimens.[1] Indeed, studies show improvements in measures of asthma control when peak flow measurements are used by patients (in relation to their personal best peak flow) to adjust medication usage.

However, despite the advantages of written plans, as discussed above, a study by the U.S. Centers for Disease Control and Prevention (CDC) analyzing data from adults and children between 2001 and 2009 in a national health interview survey showed that only one-third of patients with asthma reported being given a written asthma action plan. Furthermore, just over two-thirds of patients had been taught the appropriate response to symptoms of an asthma attack.[109]

It should be recognized that not all patients are capable of comprehending and executing complicated treatment plans. In addition, peak flow–guided self-management may lead to overtreatment with medication and the potential for increased morbidity due to adverse effects. Similarly, patients with severe asthma for whom self-management plans are more readily recommended may tend to use more oral CS, even when it may be unclear whether increased use is appropriate or medically warranted (although the increase in medication may be initially viewed as a potential benefit of peak flow monitoring). Action plans should be written using clear, simple language and should be individualized based on patients' understanding of their asthma, its severity, and their demonstrated ability to comply with instructions. The use of digital technology to help monitor inhaler use, test lung physiology remotely, and link with home and work environmental data may help predict exacerbations and alert patients to worsening asthma control.[110,111] Preliminary studies show that digital systems improve asthma control and quality of life, including a reduction in severe disease exacerbations. However, longer-term studies are needed to show a health economic impact.[112]

MANAGEMENT OF ACUTE SEVERE ASTHMA

Asthma is characterized by exacerbations of disease, which can lead to substantial morbidity, occasional mortality, and considerable medical and economic costs. Patients with asthma fear disease exacerbations, as they can be life-threatening; exacerbation-prone patients seem to be at increased risk for attacks of near-fatal asthma. Analysis of asthma mortality data has showed that patients experience worsening symptoms and deterioration in asthma control over a period of several hours to several days before the event.[113] Indeed, life-threatening episodes may develop in any asthmatic patient, particularly those patients with severe and poorly controlled disease, who frequently access the emergency room, or who are hospitalized; all are recognized to be at high risk of life-threatening events. The importance of educating all patients with asthma should not be underestimated, and healthcare professionals should identify and closely monitor such at-risk patients.

Clinical Features

Patients with a moderate exacerbation of their disease notice a deterioration in their asthma control by an increase in daytime and nocturnal symptoms of cough, chest tightness, wheezing, and dyspnea; these symptoms do not respond to the patient's usual maintenance therapy and require more reliever drug. A history of prodromal symptoms may be elicited that precedes an asthma attack, such as itching under the chin, discomfort between the scapulae, or inexplicable fear (impending doom). A fall in home peak flow recordings also signifies a worsening of asthma. The GINA guidelines classify exacerbations based on the peak flow into mild (PEF >80% predicted), moderate (PEF between 60% and 80% predicted), and acute severe (PEF <60% predicted).[1]

Patients may become so breathless in acute severe exacerbations that they become exhausted, unable to talk freely in complete sentences, and show life-threatening features of confusion, agitation, and cyanosis. Clinical examination usually shows an increased respiratory rate, chest hyperinflation, and tachycardia. In acute severe asthma, pulsus paradoxus (accentuated decrease in systolic blood pressure of >10 mm Hg during inspiration), may be present. Life-threatening signs include a silent chest, bradycardia, and hypotension. Evaluation shows a marked fall in PEF and spirometric values; oxygen saturation on room air may be reduced, and arterial blood gases may reveal a low Pa_{O_2}. Initially, Pa_{CO_2} is low due to hyperventilation. In life-threatening situations, PEF is <30% predicted; oxygen saturation (Sa_{O_2}) measured by pulse oximetry is <92%; and arterial blood gases on room air reveal a Pa_{O_2} <60 mm Hg (8 kPa). A rising Pa_{CO_2} indicates impending respiratory failure and requires immediate monitoring and therapy. A chest radiograph is not routinely recommended in the absence of a suspected pneumothorax, pulmonary consolidation, failure to respond to treatment satisfactorily, or a requirement for mechanical ventilation.

Pharmacologic Treatment

The cornerstone of therapy for worsening asthma control requires the escalation of both ICS and quick-relief inhaled β_2-agonists.[1] Exacerbations of asthma should never be treated by escalating bronchodilators alone. Asthma fatalities usually result when patients fail to promptly seek medical attention. Studies have shown patients dying from asthma commonly self-medicate with escalating doses of reliever bronchodilator medication in the days preceding an asthma attack. A short course of oral CS therapy for at least several days may be needed to control and prevent a mild to moderate exacerbation; tapering of the dose should be undertaken with close outpatient follow-up. Very mild or subacute exacerbations with mild persistent disease may be managed in some cases by escalating the dose of ICS in cases in which patients are taking low-dose CS. In less severe exacerbations, patients who promptly respond to treatment in the emergency department may be discharged, but close outpatient follow-up is essential.

In patients with an acute severe exacerbation presenting to the emergency department, oxygen at high concentrations and high flows should be given continuously by face mask to achieve oxygen saturations (Sp_{O_2}) between 94% and 98%. Hypoxemia is to be avoided at all costs, as patients die from hypoxemia in acute asthma. Oxygen therapy is critical to prevent death in severe acute asthma, so continuous monitoring of oxygen saturation is needed until there is a meaningful response to treatment.

High doses of inhaled SABA, given either by nebulizer (oxygen-driven) or via a pMDI with a spacer, should be the first-line agents in acute asthma and should be administered as early as possible. While generally well tolerated, nebulized bronchodilators occasionally cause arrhythmias; continuous electrocardiogram monitoring is required. In those patients in whom inhaled therapy cannot be used reliably, or in severely ill patients with impending respiratory failure, intravenous β_2-agonists may be given. In patients not responding to treatment, a nebulized anticholinergic (e.g., ipratropium bromide) may be added to provide additional bronchodilation. Systemic CS should be given in adequate doses in all cases of acute severe asthma for at least 5 days or until recovery; the CS should be tapered after this response over a 2-week period, particularly in cases of severe asthma exacerbations. In patients unable to take oral CS, intravenous therapy (e.g., hydrocortisone) should be administered in the emergency department.

A single dose of intravenous magnesium sulfate for patients has been shown to be effective when added to inhaled β_2-agonists. It is relatively well tolerated and can be considered in patients with acute severe asthma who have not had an initial good response to inhaled bronchodilator therapy or in those with life-threatening features.

Patients should be referred to the intensive care unit for intubation and mechanical ventilation if they have acute severe or life-threatening asthma that fails to respond to therapy, as indicated by a deteriorating PEF, worsening hypoxemia, a normal or rising Pa_{CO_2}, poor respiratory effort, or exhaustion or confusion. Intravenous aminophylline may be used, but the risks of toxicity are much greater than for inhaled β_2-adrenergic agonists. Sedatives should never be given, as they may depress ventilation. Antibiotics should not be routinely administered in the absence of clinical or radiologic signs of pneumonia.

CHAPTER 46

Allergic Bronchopulmonary Aspergillosis (Mycosis) and Severe Asthma with Fungal Sensitivity

Geoffrey L. Chupp

INTRODUCTION

Allergic bronchopulmonary aspergillosis (ABPA) is an idiopathic inflammatory disease of the lung, characterized by an allergic inflammatory response to colonization of the airways by *Aspergillus fumigatus* or other fungi. The entity was first described in 1952 by Hinson et al., and then again in 1967, when Scadding recognized an association between the disease and proximal bronchiectasis in areas previously affected by infiltrates (predominantly in the upper lobes).[1,2] The first adult case of ABPA was reported in the United States in 1968.[3] Although most cases entail hypersensitivity to *Aspergillus* spp. (i.e., *A. fumigatus* or *niger*), the finding of a virtually identical clinical syndrome associated with immune sensitivity to *Candida albicans* (most commonly), *Helminthosporium*, *Alternaria*, *Curvularia lunata*, *Drechslera hawaiiensis*, *Stemphylium languinosum*, *Saccharomyces cerevisiae*, or *Pseudallescheria boydii* has led some to use the term *allergic bronchopulmonary mycosis* to describe the syndrome.[4] However, since the predominant causative organism is *A. fumigatus* (and the commercially available laboratory testing is for this organism and *A. niger*), ABPA is primarily designated as the diagnosis. In addition, a recently recognized entity appears to be on the continuum between fungal allergy, at one end, and ABPA at the other: severe asthma with fungal sensitivity (SAFS).[5]

The precise prevalence of ABPA is unknown, in part due to variability in diagnostic criteria used in various studies, the lack of distinction between ABPA and mold-sensitive asthma, and delays in the diagnosis of patients with long-standing disease; however, it is clear that ABPA is a relatively common entity. Estimates are that true ABPA complicates approximately 7% to 14% of cases of chronic steroid-dependent asthma and approximately 7% to 15% of cases of cystic fibrosis (CF). Therefore, it is commonly encountered by pulmonologists and allergists.[6,7]

Most cases of ABPA are recognized in the third to fifth decade of life, but the disease can also present during childhood. In some patients, it is likely that ABPA starts early in life and continues, unrecognized, until adulthood. Interestingly, familial cases have been reported, suggesting that genetic factors may underlie the development of ABPA.[8,9] The spectrum of disease is broad, which can complicate the diagnosis and initiation of corticosteroid-sparing therapy. Patients may be asymptomatic, have mild to moderate asthma, or have severe and debilitating disease that leads to severe bronchiectasis, mucoid *Pseudomonas* colonization, and the need for lung transplantation. However, if recognized early and managed aggressively, ABPA is treatable, it may enter into remission, and progressive lung damage can be avoided.

For the purposes of this discussion, the focus will be on ABPA. However, clinicians should be cognizant that diagnostic testing for other fungi should be pursued when organisms other than *Aspergillus* spp. are suspected. In addition, in patients that don't quite meet criteria of ABPA, a diagnosis of SAFS should be considered as it will affect clinical management.

PATHOGENESIS

Although the pathogenesis of ABPA is poorly understood, it is believed to be the result of an exaggerated immunologic reaction to chronic airway colonization by *Aspergillus* (or other relevant fungal) species.[10] *Aspergillus* spp. are globally ubiquitous, thermotolerant fungi that reside in decaying organic matter and colonize most domestic environments, including carpets and air duct systems.

In humans, airborne *Aspergillus* spores or conidia that are inhaled are immunologically inert. In normal individuals they are cleared by innate immune system mechanisms that maintain airway homeostasis managed by neutrophils, macrophages, and dendritic cells. The result is immunologic tolerance to the presence of the spores. However, in susceptible individuals, conidia colonize airways and germinate into somatic hyphae, stimulating a chronic allergic inflammatory response that drives IgE production and eosinophilic inflammation. This results in tissue injury and the clinical features of ABPA.[7] In contrast to a true infection in which fungal hyphae invade the lung parenchyma, colonization of the airways with germinating fungal spores represents an abnormal state that remains within the airway and promotes an exaggerated Th2 inflammatory response. While details of the mechanisms that drive this process remain poorly understood, it appears that susceptibility to *Aspergillus* colonization and development of clinical disease depend on host factors that include genetic risk, T-cell responsiveness to *Aspergillus* antigens, the magnitude of tissue response to *Aspergillus*, and the level of environmental exposure to this ubiquitous fungus.

Investigations into the genetic risk factors that are associated with ABPA have identified several candidate genes. This suggests that the pathogenesis of ABPA is dependent on both host and environmental factors.[11] Best characterized is the association between gene mutations in the CF transmembrane conductance regulator (CFTR) and the pathogenesis of ABPA.[12,13] CFTR mutations are more common among patients with ABPA compared with the general population or with individuals with severe asthma without sensitivity to *A. fumigatus*. Another genetic link to ABPA is that Th2-type T-cell reactivity to selected *Aspergillus* antigens is determined by the presence of MHC class II DR2 or DR5 alleles, which may predispose patients to the disease, whereas the MHC DQ2 allele may be protective.[14,15] In addition, investigators have determined that there is an increased prevalence of polymorphisms in the promoter region of the pathogen-associated molecular pattern receptor Toll-like receptor 9 (TLR9) in individuals with ABPA compared with controls or patients with SAFS.[16] We recently determined that children with severe asthma and ABPA are more likely to carry the chitotriosidase 1 (CHIT1) exon 10 mutation.[17,18] Individuals with the exon 10 mutation have lower levels of, or lack, chitinase activity and are unable to degrade chitin, a structural polysaccharide in the cell wall of lower life forms such as *A. fumigatus*.[19–21]

At the microscopic level, ABPA is characterized by an intense eosinophilic and mononuclear cell inflammatory response, leading to areas of parenchymal scarring, airway remodeling, and bronchiectasis.[22,23] Immunologic studies demonstrate the presence of a type I hypersensitivity reaction, with elevated serum levels of total IgE and *A. fumigatus*–specific IgE in individuals with ABPA (Fig. 46-1). In addition, patients have evidence of an exaggerated type III hypersensitivity reaction, indicated by the presence of *A. fumigatus*–specific IgG antibodies (classically called "precipitins" or precipitating antibodies) and circulating immune complexes during

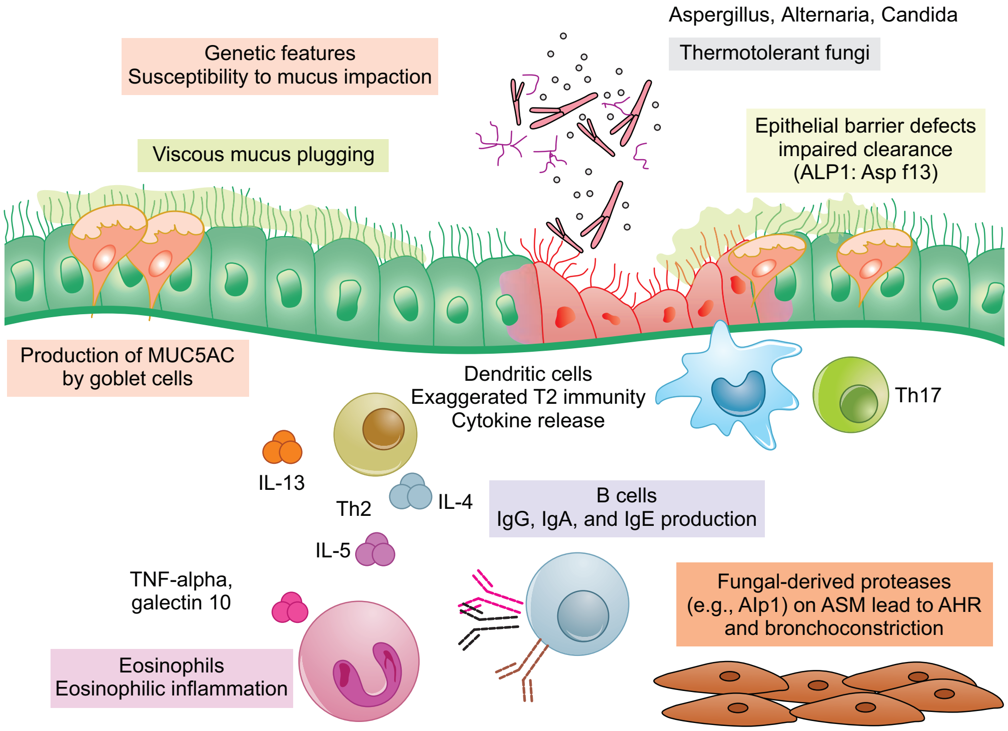

Figure 46-1 Inflammatory response ABPA. In susceptible individuals, conidia germinate into somatic hyphae. These hyphae then stimulate a chronic allergic inflammatory response that drives Th2 and Th17 with subsequent IgE production and neutrophilic and eosinophilic inflammation. This sequence of events eventually leads to tissue injury and bronchiectasis. *(Reproduced with permission from Wardlaw AJ, Rick EM, Pur Ozyigit L, et al. New Perspectives in the Diagnosis and Management of Allergic Fungal Airway Disease. J Asthma Allergy. 2021;14:557–573.)*

disease exacerbations. A type IV cell-mediated immune reaction also may be at work, based on the finding of dual (immediate and delayed) cutaneous reactions and in vitro lymphocyte transformation to *A. fumigatus* antigen stimulation in some patients.[24,25]

A substantial amount of research has been done on the immune response in ABPA, demonstrating that several cell types and pathways are involved in the pathogenesis of this destructive variant of asthma.[19,20] A pathogenetic role for helper T lymphocytes is suggested by a number of findings, including the presence of increased numbers of airway Th2 cells and elevated levels of soluble interleukin 2 (Il-2) receptors (suggesting T-cell activation) in the circulation of persons with active ABPA;[26] the derivation of *A. fumigatus*–specific T-cell clones with T helper 2 (Th2) patterns of cytokine production from the blood of patients with ABPA;[27,28] positive correlations between activated T-cell number, levels of the T cell–derived cytokines IL-4 and IL-5, and the elevated numbers of airway eosinophils in the disease; the critical role IL-5 plays in murine models of ABPA;[29–36] and increased reactivity of Th2 cells to *A. fumigatus* antigens among patients with ABPA as compared with patients with asthma and skin reactivity to *Aspergillus*.

In addition to lymphocytes, eosinophils and basophils may contribute to local airway injury; neutrophils also likely play a role in airway inflammation and tissue damage in ABPA. This is evidenced by the fact that sputum IL-8 levels correlate with sputum neutrophilia, matrix metalloproteinase levels, and FEV_1 among patients with ABPA.[37,38]

It is also clear that the fungus itself contributes substantially to the pathogenesis of disease. *A. fumigatus*–derived proteases contribute to epithelial cell injury and protective barrier disruption, triggering inflammation by allowing increased penetration of fungal antigens into the airway wall, which leads to immune hypersensitivity.[39] *Aspergillus*-derived proteases may also stimulate proinflammatory cytokines, such as IL-8, and release of growth factors; proteases also cause tissue damage that leads to bronchiectasis.[38]

A variety of other *Aspergillus*-derived antigens, including cytotoxins and heat shock proteins (demonstrated by their ability to bind IgE and IgG derived from the blood of patients with ABPA), also have been shown to drive both the IgE (hypersensitivity) and IgG immune responses. *A. fumigatus*–derived proteases with antibody-binding capacity also may amplify the inflammatory response. Other *A. fumigatus* antigens, such as Aspf1 (a cytotoxic protein), Aspf2 (a fibrinogen–binding protein), Aspf5 (a metalloprotease), Aspf6 (manganese superoxide dismutase), Aspf8 (a ribosomal protein), Aspf13 and Aspf18 (serine proteases), and Aspf3 and Aspf4, also have been implicated in the pathobiology of ABPA. Finally, host response to *Aspergillus fumigatus* antigens includes surfactant proteins (SP) A and D, which may play a protective role against ABPA by interfering with binding between *A. fumigatus* antigens and IgE. Notably, however, SPD levels do not correlate with acute exacerbations of ABPA in humans.[40–42]

CLINICAL FEATURES

Although ABPA typically presents in patients with a history of difficult-to-control asthma, the spectrum of presentation is highly variable and should be considered in any patient with difficult-to-control asthma and hypersensitivity to *A. fumigatus*.[42] Typical presenting complaints are often nonspecific and include dyspnea, wheezing, poor asthma control, cough (sometimes productive of thick, brown mucus plugs), malaise, low-grade fever, and occasionally, hemoptysis. There may be an antecedent history of recurrent asthma exacerbations in conjunction with pneumonias without a culture-identified bacterial source. In addition, atopy with rhinitis, drug allergy, and/or allergic conjunctivitis are common. It is often not until a patient has been repeatedly ill over weeks to months and unresponsive to standard treatments that the diagnosis is considered.[43] As patients with SAFS have the same clinical presentation, differentiation from ABPA is based on interpretation of laboratory testing and radiographic studies.[42]

TABLE 46-1 Criteria for the Diagnosis of ABPA

Seropositive ABPA (ABPA-S)
- History of asthma (usually difficult to control)
- Elevated total serum IgE (usually >1000 IU/mL)
- Immediate skin test reactivity to *Aspergillus fumigatus or* elevated specific serum IgE to *A. fumigatus*
- Presence of serum precipitins (by gel diffusion) or elevated specific serum IgG to *A. fumigatus*

ABPA central bronchiectasis (ABPA-CB)
- Above criteria are positive
- Central bronchiectasis by high-resolution CT scan or chest radiograph

Other supportive clinical findings
- Peripheral blood eosinophilia (may be absent if patient is on oral or inhaled corticosteroids)
- Patchy, fleeting infiltrates (may be absent if patient is on oral corticosteroids)
- Expectoration of mucus plugs or bronchial casts
- Mucoid-impacted bronchi evident on radiographic studies
- Sputum culture positive for *A. fumigatus*

Diagnostic Guidelines

In general, the diagnosis of ABPA is based on appropriate clinical features in combination with supporting radiologic and serologic findings. While there are no specific diagnostic criteria, similar guidelines have been proposed by multiple expert panels to aid clinicians in the diagnosis of ABPA (Table 46-1).[22,44] These guidelines have evolved over time and have been updated by several societies. There is no agreement on clinical criteria that should trigger screening for ABPA, but in most asthma centers, all asthmatics with difficult-to-control asthma are screened by checking for an elevated eosinophil count, total IgE, and specific IgE *A. fumigatus*, *A. Niger*, and *Alternaria* spp.

Using the Patterson criteria, ABPA is classified into two different subtypes: ABPA-seropositive (S) and ABPA-central bronchiectasis (CB). Patients with ABPA-S usually display all of the following diagnostic criteria proposed by Greenberger and Patterson: (1) history of asthma; (2) total IgE >1000 IU/mL; (3) elevated serum anti-*AF* IgE and IgG (twofold higher than *A. fumigatus* allergic asthma controls); (4) positive immediate hypersensitivity skin test to *A. fumigatus*; and/or (5) serum IgG precipitating antibodies against *A. fumigatus*. The last criterion is considered positive when the double gel diffusion, the enzyme-linked immunoassay (ELISA), or the fluorescent enzyme immunoassay (FEIA) is positive for anti-*AF* IgG antibodies.[45] Patients with ABPA-S have normal chest radiographic studies, with no evidence of bronchiectasis. Patients with ABPA-S tend to have fewer symptoms, lower IgE levels, less severe airflow obstruction, and fewer exacerbations than patients with ABPA-CB.[46] In contrast, patients with ABPA-CB are positive for all of the criteria of ABPA-S and have features of advanced disease including bronchiectasis on high-resolution CT scanning or chest x-ray.[47,48] These patients may also expectorate mucus plugs or bronchial casts and are sputum culture positive for *A. fumigatus*. Although IgE levels fluctuate with disease activity, a normal IgE level in a symptomatic, untreated patient with asthma virtually excludes the diagnosis.[49] It remains unclear whether ABPA-S is a milder form of the disease (e.g., representing a different host response) or an earlier stage of illness. Identification of *Aspergillus* (or other relevant fungus) in the sputum and dual (immediate and delayed) cutaneous reactions to challenge with *Aspergillus* (by prick test or intradermal) also are common clinical features of ABPA. Rare cases lacking a history of asthma, but meeting the other major diagnostic criteria, have been reported.[43]

Severe Asthma with Fungal Sensitivity

The broad spectrum of clinical, laboratory, and radiographic abnormalities evident in patients with asthma and fungal allergy has led to the description of additional diagnostic categories of allergic fungal disease. The most clinically relevant of these diagnoses is based on studies that demonstrate that antifungal therapies are effective in patients with poorly controlled asthma who have some of the criteria for ABPA-S but do not reach the threshold for diagnosis. These patients have been designated as having SAFS. Whether SAFS is a unique disease or is on the continuum from asthma to ABPA is not known. However, the primary distinction between SAFS and ABPA is that patients with SAFS have a milder allergic reaction and lack the exaggerated IgG response that is typical of patients with ABPA. Patients with SAFS can be difficult to distinguish from patients with ABPA-S, as their clinical features are identical and both lack radiographic evidence of bronchiectasis.

The diagnosis of SAFS is based on the interpretation of *Aspergillus*-specific immunologic studies. The diagnostic criteria for SAFS (Table 46-2) overlap substantially with ABPA-S and include: (1) severe uncontrolled asthma (treatment requirement of >500 μg/d of fluticasone or the equivalent, need for near continuous oral corticosteroids for 6 months or ≥2 oral steroid tapers per year); (2) positive skin prick test or RAST for *A. fumigatus* or other fungi; (3) elevated total serum IgE, but <417 IU/mL or <1000 ng/mL; and (4) absence of IgG against *A. fumigatus* (by ELISA, gel diffusion, or FEIA).

Typically, patients with SAFS have normal radiographic studies and a milder immunologic response similar to patients with milder asthma. Although it remains unclear whether these patients are on the continuum from asthma to ABPA or are at risk of progressing to ABPA, the clinical importance of identifying patients with SAFS is based on several studies showing that antifungal therapies can improve asthma control and reduce oral corticosteroid exposure.[50–52]

The differential diagnosis of ABPA is broad and includes corticosteroid-dependent asthma without ABPA, SAFS, chronic obstructive pulmonary disease (COPD), chronic necrotizing aspergillosis, tuberculosis, parasitic infections, hypersensitivity pneumonitis, Churg–Strauss syndrome, acute eosinophilic pneumonia (including drug-induced pneumonitis), chronic eosinophilic pneumonia, lymphoma, idiopathic hypereosinophilic syndrome, autoimmune disease, crack cocaine use, CF, and other causes of bronchiectasis. The diagnosis of ABPA in patients with mold-sensitive asthma and

TABLE 46-2 Criteria for the Diagnosis of Severe Asthma with Fungal Sensitivity (SAFS)

1. History of poorly controlled asthma despite >500 μg/d of fluticasone or the equivalent, near continuous oral corticosteroids (>50% of the time), or ≥2 oral steroid tapers per year
2. Total serum IgE <1000 IU/mL
3. Positive immediate skin test reactivity to *Aspergillus fumigatus or* elevated specific serum IgE to *A. fumigatus*
4. Absence of serum precipitins (by gel diffusion) and elevated specific serum IgG to *A. fumigatus*
5. No radiographic evidence of bronchiectasis or infiltrates

CF poses a particular diagnostic challenge. In asthmatics, by definition, bronchiectasis is absent and serum precipitating antibodies to *Aspergillus* spp. may be present in up to 25% of patients, making the distinction from ABPA-S difficult.

Persons with mold-sensitive asthma or ABPA may have peripheral blood eosinophilia and/or elevated serum total IgE levels. However, most persons with ABPA have 2- to 20-fold higher serum levels of *Aspergillus*-specific IgE and total IgE than do mold-sensitive asthmatics without ABPA.

A diagnostic conundrum occurs when considering the diagnosis of ABPA in patients with CF, because patients with CF alone may manifest chronic airflow obstruction, recurrent exacerbations with infections and/or bronchoconstriction, underlying bronchiectasis, pulmonary infiltrates, chronic sputum production, *Aspergillus* colonization of the airways, and positive serum precipitins. Distinguishing ABPA in patients with CF is critical because infectious CF exacerbations and ABPA require different treatments. The steroid treatment required for ABPA may be detrimental in the setting of infection, yet antibiotics alone given for infection may be inadequate to control the inflammation associated with ABPA. Among patients with CF, factors associated with the risk of ABPA include adolescent age, atopy, severe lung disease, and colonization with *Pseudomonas aeruginosa*. ABPA should be suspected in patients with CF who develop clinical deterioration, exhibit a greater than fourfold increase in total serum IgE (especially >1000 IU/mL), have immediate cutaneous reactivity to *Aspergillus* or increased *Aspergillus*-specific IgE or IgG, and show a change in baseline chest radiograph. Annual screening of total serum IgE is recommended; if the level rises >500 IU/mL, immediate cutaneous hypersensitivity testing for reactivity to *A. fumigatus* or testing for serum anti–*A. fumigatus* IgE is recommended.[13,53] The titer of IgE reactive against the purified *Aspergillus* allergens Aspf3 and Aspf4 may be useful in distinguishing patients with ABPA and CF or *Aspergillus*-sensitive asthma from patients without ABPA, with rising or high titers being more indicative of ABPA than a bacterial-driven flare of CF.[12]

TABLE 46-3 Clinical Stages of ABPA

Stage I: Acute
- Acute asthma symptoms
- Elevated serum IgE (>1000 IU/mL)
- Peripheral blood eosinophilia (may be absent in patients treated with oral corticosteroids)
- Fleeting infiltrates on chest radiograph (may be absent in patients treated with oral corticosteroids)
- Positive specific IgE, IgG, skin test reactivity, or precipitins to *Aspergillus fumigatus*
- Responds to steroids/antifungal therapy

Stage II: Remission
- Resolution of symptoms
- Resolution of pulmonary infiltrates
- Improvement in eosinophilia and *A. fumigatus* specific blood abnormalities

Stage III: Exacerbation/Recurrence
- Recurrence/worsening of clinical symptoms
- Recurrent pulmonary infiltrates
- Rising IgE levels

Stage IV: Steroid-Dependent Asthma
- Refractory steroid-dependent asthma
- Persistently elevated serum IgE levels
- Persistently elevated *A. fumigatus*–specific blood abnormalities

Stage V: Fibrotic Lung Disease
- Refractory, steroid-dependent asthma
- Fibrotic lung disease (irreversible obstructive and restrictive defects with impaired diffusing capacity)
- Chronic bronchiectasis symptoms (sputum production, frequent infections)

Clinical Staging of ABPA

Five clinical stages of ABPA have been recognized based on clinical, serologic, and radiographic characteristics (Table 46-3). A modified version proposed by the International Society for Human and Animal Mycology (ISHAM) has been developed but has not been widely adopted.[22,54]

Using the classic staging system, stage I, the *acute* stage, is characterized by symptoms of moderate to severe asthma, elevated total IgE (typically >1000 IU/mL), elevated anti–*A. fumigatus* IgE or hypersensitivity skin test to *A. fumigatus*, infiltrates on chest radiograph (with or without proximal bronchiectasis), peripheral blood eosinophilia (frequently >2000/mm^3), and positive precipitating or anti-IgG antibodies to *A. fumigatus* (up to fivefold concentration of serum may be required for detection of the precipitating antibodies).

Patients with stage II ABPA have disease that is in *remission*. This stage is characterized by the resolution of symptoms, radiographic clearing, and decreased of total IgE levels. Remissions are of varying length, may last several months to years, or may be permanent, allowing corticosteroid treatment to be tapered or discontinued.

Patients with stage III ABPA have *recurrent* disease or disease *exacerbations*. This stage of ABPA is common and is characterized by development of new pulmonary infiltrates and, usually, a substantial increase in total IgE. Elevation of IgE may precede clinical or radiologic worsening during this stage; an isolated increase in the severity of bronchospasm does not constitute an exacerbation in the absence of a change in biomarkers. Although a majority of disease exacerbations are associated with a concomitant increase in symptoms, exacerbations may occur in the absence of any increase in symptoms. Indeed, since up to one-third of patients with radiographic infiltrates may be asymptomatic, evolving progressive lung damage may remain unrecognized. Total serum IgE levels, pulmonary function testing, and chest imaging should be monitored intermittently. *Aspergillus*-specific IgA levels may also be elevated in an exacerbation of ABPA. Exacerbations are more likely to occur seasonally or in environments where mold counts are high.

Stage IV ABPA is defined as *steroid-dependent asthma*. In stage IV disease, total IgE, *Aspergillus* precipitins, and *Aspergillus*-specific IgE and IgG typically remain elevated, despite chronic steroid therapy. During this phase, the frequency of exacerbations may increase, become chronic, and be difficult to control.

Stage V is defined as *pulmonary fibrosis*. Stage V patients have chronic symptoms consistent with bronchiectasis that include cough and dyspnea. These patients are often steroid dependent because of persistent bronchospasm and have chronic sputum production, recurrent respiratory infections, and irreversible pulmonary function abnormalities (obstruction, restriction, and/or gas exchange abnormalities), and may have cyanosis or clubbing. The serologic profile of patients with stage IV disease is also evident in stage V. Stage V disease is generally thought to be the consequence of longstanding, often unrecognized disease, but it may occur occasionally among patients with little prior clinical evidence to suggest the diagnosis.

DIAGNOSTIC STUDIES

In addition to the blood abnormalities described earlier in this chapter, analysis of BAL fluid from patients with ABPA often reveals moderate eosinophilia (especially in steroid-naive patients) and increased levels of *Aspergillus*-specific IgE and IgA, but not IgG.[55] On bronchoscopy, mucoid impaction may be evident, and bronchial brushings may reveal mucus that contains aggregates of eosinophils, fungal hyphae, and eosinophil-derived Charcot–Leyden crystals. The finding of hyphae-filled mucus plugs is considered pathognomonic for ABPA. Pulmonary function tests typically reveal an obstructive ventilatory defect (due to bronchospasm or mucus impaction of the bronchi) during stages I, III, IV, and often V, and may not correlate with the duration of ABPA or asthma. Patients with stage V disease typically also have a restrictive ventilatory defect and a reduced DL_{CO}.

The typical radiographic manifestations of ABPA include parenchymal infiltrates and bronchiectasis (Figs. 46-2C and 46-3). The infiltrates are often irregular and transient (1–6 weeks) and have a predilection for the upper lobes, although all lobes may be affected. The bronchiectasis is classically cylindric and proximal (central), occurring within the proximal two-thirds of the lung (Fig. 46-2B). Mucoid impaction in dilated bronchi leads to a characteristic (but nonspecific) radiographic appearance of ABPA termed the "finger in glove" opacity on chest radiograph. "Tramline shadows" (parallel linear shadows extending from the hilum in bronchial distribution and reflecting longitudinal views of inflamed, edematous bronchi), "toothpaste shadows" (representing mucoid impaction of the bronchi), "ring shadows" (dilated bronchi with inflamed bronchial walls seen on end), local consolidation, or lobar collapse also are common features. Involvement of the small airways may lead to centrilobular nodules and branching tree-in-bud opacities (Fig. 46-2C). Less

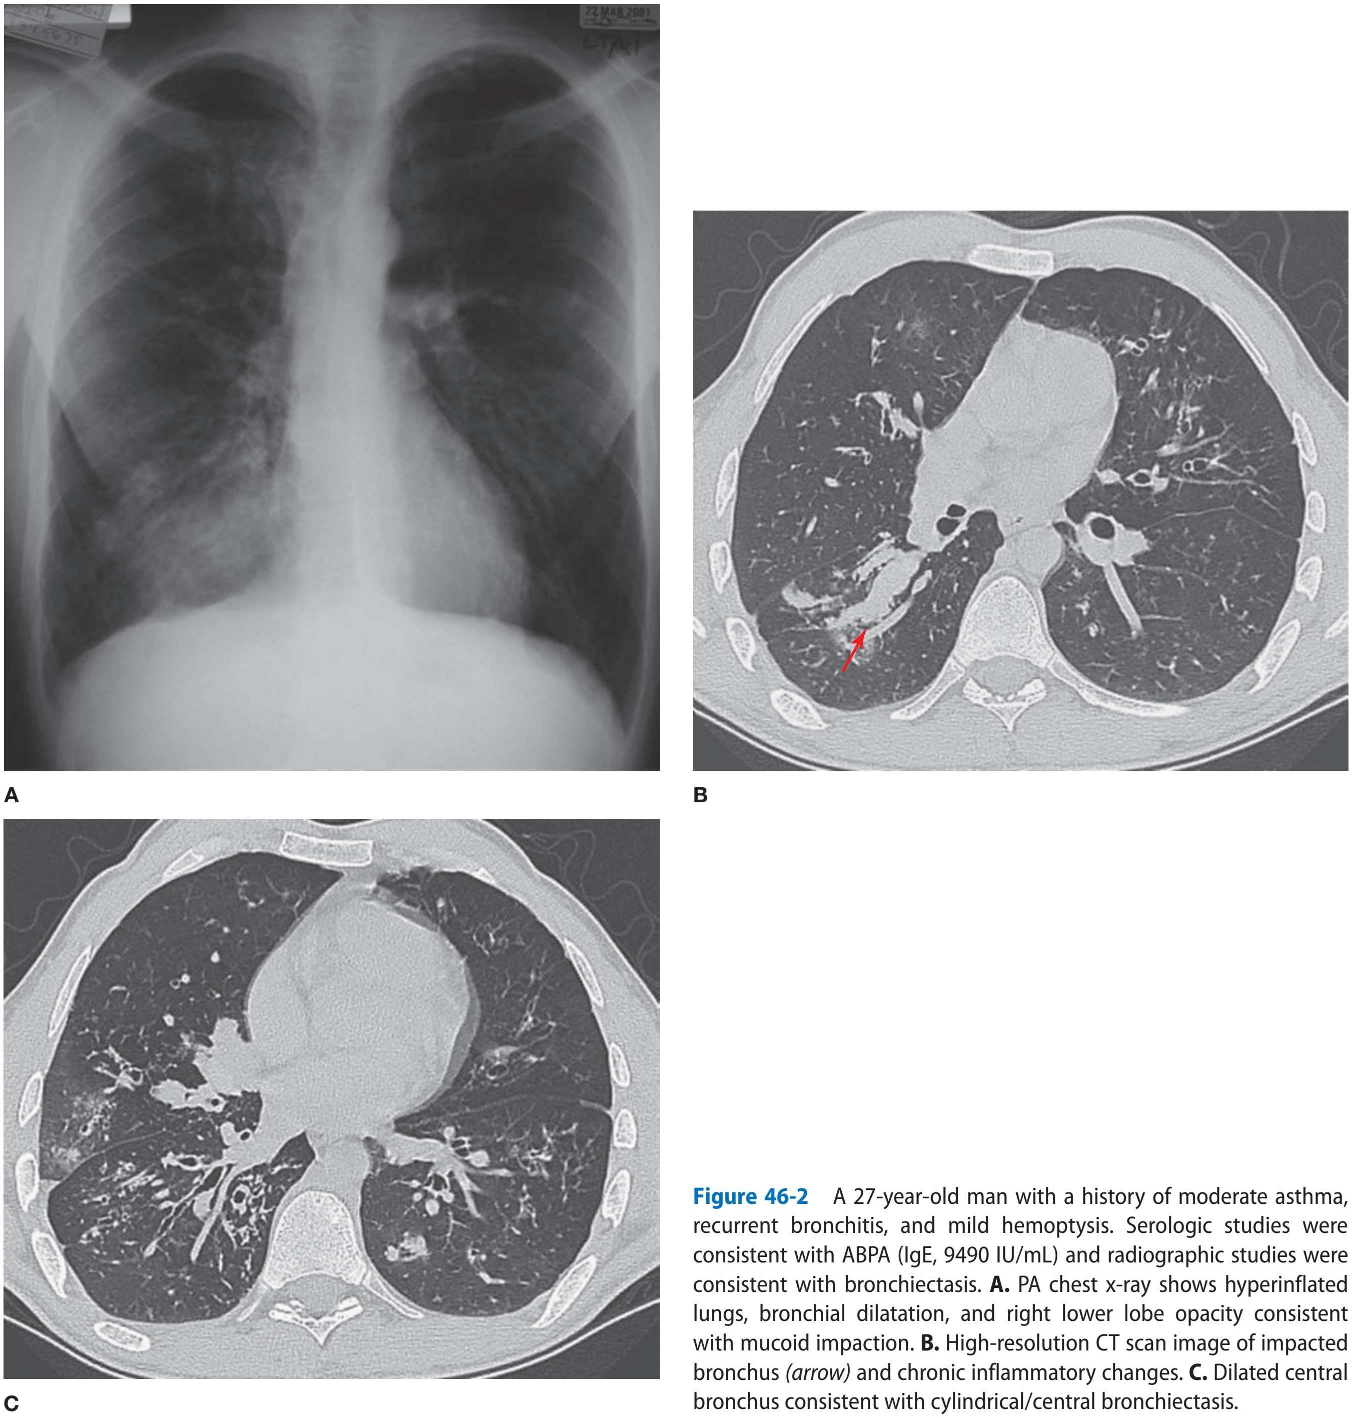

Figure 46-2 A 27-year-old man with a history of moderate asthma, recurrent bronchitis, and mild hemoptysis. Serologic studies were consistent with ABPA (IgE, 9490 IU/mL) and radiographic studies were consistent with bronchiectasis. **A.** PA chest x-ray shows hyperinflated lungs, bronchial dilatation, and right lower lobe opacity consistent with mucoid impaction. **B.** High-resolution CT scan image of impacted bronchus *(arrow)* and chronic inflammatory changes. **C.** Dilated central bronchus consistent with cylindrical/central bronchiectasis.

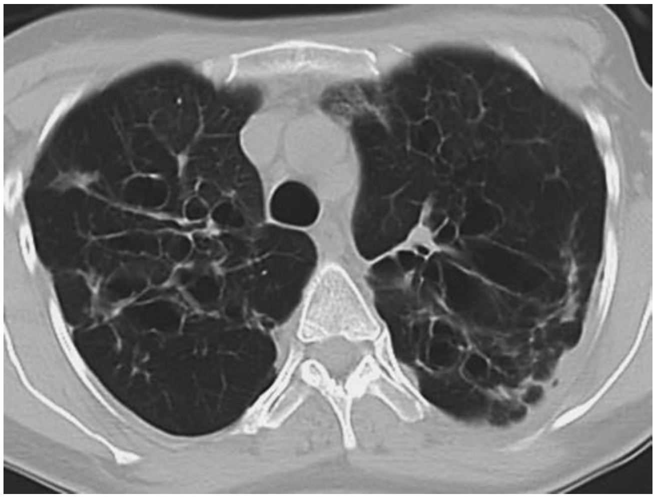

Figure 46-3 Representative CT image of the lungs of a 41-year-old woman who presented with stage V ABPA after a long history of mild asthma (IgE, 1500 IU/mL). Pulmonary function studies demonstrated severe combined obstructive and restrictive defects. CT shows bilateral upper lobe scarring and emphysematous changes.

common radiographic findings include bullous changes, pneumothorax, pleural effusion, cavitating nodular lesions, aspergilloma (Fig. 46-4), and migratory parenchymal opacities, with a ground-glass appearance. High-resolution CT scanning is the most reliable noninvasive means of detecting proximal bronchiectasis. It has largely supplanted chest radiographs to monitor ABPA patients over time and generally correlates with IgE and eosinophil levels.[56]

Surgical lung biopsy is usually not required to establish the diagnosis of ABPA and may not show specific findings, so it is generally not recommended. Histopathologic findings include intense bronchocentric inflammation with prominent eosinophilia, as well as lymphocytes, plasma cells, and monocytes. Bronchi may be filled and/or impacted with copious mucus plugs containing fibrin, Charcot–Leyden crystals, Curschmann spirals, and fungal hyphae. Bronchiectasis of segmental and subsegmental bronchi may be evident. Regions of bronchocentric granulomatosis, eosinophilic pneumonia, eosinophilic microabscesses, lymphocytic or desquamative interstitial pneumonitis, proliferative or obliterative bronchiolitis, lipoid pneumonia, or interstitial fibrosis also may be seen.

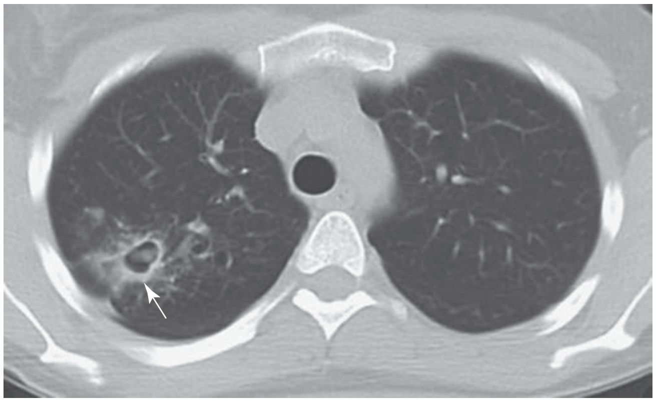

Figure 46-4 A 21-year-old woman with ABPA, who responded to treatment with oral corticosteroids and chronic antifungal therapy and then developed an aspergilloma *(arrow)* and hemoptysis. Amphotericin paste injection failed, and the patient ultimately underwent a right upper lobe lobectomy for chronic hemoptysis.

TREATMENT

The goals of treatment for individuals with ABPA consist of controlling symptoms, preventing exacerbations, and preserving normal lung function.

Systemic corticosteroids are the mainstay of therapy for ABPA. Without treatment, ABPA may cause significant irreversible lung damage due to bronchiectasis and pulmonary fibrosis. Therefore, initiation of appropriate treatment early in the course of disease is essential. Although most data are derived from small uncontrolled trials and definitive proof that corticosteroid therapy prevents the development of central bronchiectasis is lacking, retrospective studies suggest that early therapeutic intervention using corticosteroids reduces progression or irreversible lung damage.

Therapy for stage I or III disease (acute presentation and exacerbations of disease) should include prednisone, 0.5 to 1 mg/kg a day for 2 weeks, followed by 0.5 mg/kg every other day for 6 to 8 weeks with a taper (by 5–10 mg every 2 weeks) over weeks to months. The duration of treatment and pace of taper must be guided by activity and severity of disease with an aim of minimizing cumulative exposure to systemic corticosteroids. A low maintenance dose (e.g., 5.0–7.5 mg/d) may be required to control the disease and prevent recurrence in some patients.

Corticosteroid therapy leads to relief of symptoms, decreases in airflow obstruction, greater than 35% reduction in serum IgE, reductions in peripheral blood eosinophils, and resolution of pulmonary infiltrates. IgE levels should be monitored within a few months of an acute episode or exacerbation and should be followed periodically thereafter since levels may rise, reflecting increasing disease activity prior to an exacerbation in the absence of clinical symptoms. Escalation of steroid therapy should be considered if IgE levels rise more than 100%. Pulmonary function testing should be followed closely as well and imaging should be conducted intermittently if the disease is quiescent.

Although treatment of acute exacerbations is believed to be helpful in preventing fibrotic complications of ABPA, it is not known if early detection and treatment of disease flares has any effect on disease progression. Therefore, high-dose systemic corticosteroid treatment of asymptomatic individuals is not recommended. Patients with CF and ABPA flares may derive symptomatic or functional improvement from steroid treatment. However, patients with CF who are on steroids should be followed closely for the development of invasive or semi-invasive aspergillosis. It is unclear whether development of ABPA alters the course of CF disease progression.

Although not advocated as primary treatment, inhaled corticosteroids are useful for control of bronchospasm and may help minimize the dose of systemic steroid necessary to control symptoms. They can spare the need for systemic steroids during the treatment of ABPA exacerbations and the chronic management of symptoms. Adjuvant treatment with bronchodilators and antibiotics also helps control bronchospasm and secondary respiratory infections.

The development of oral antifungal agents has brought new hope to patients with ABPA.[57,58] Even though the current concept of ABPA is not that of a classic "infection," evidence is mounting to support use of the antifungal agent, itraconazole, in patients with ABPA. The presumed mechanism of action is that these agents minimize the degree of fungal colonization.

In one randomized controlled study, itraconazole (200 mg twice daily for 16 weeks) led to significant reductions in corticosteroid dose, decreased IgE levels, greater resolution of pulmonary infiltrates, and gains in exercise tolerance or pulmonary function.[59] Several clinical studies have demonstrated that treatment with itraconazole also reduces *Aspergillus* antibody titers and eosinophilia compared with placebo.[57]

Itraconazole treatment (200 mg/d or every other day) is generally recommended for patients with ABPA who are steroid dependent, who have frequent relapses, and in whom the cost and risks are thought not to outweigh the potential benefits. Itraconazole has also demonstrated utility in ABPA associated with CF. If itraconazole is used, steady-state blood levels can be checked after 1 to 2 weeks, 4 h after the dose is given, to assess drug absorption.[60]

Since itraconazole interferes with the hepatic metabolism of several medications, including cyclosporine, oral hypoglycemics, tacrolimus, terfenadine, cisapride, and midazolam, particular caution should be exercised with its use among patients taking any of these medications. Physicians must also be mindful of adrenal insufficiency associated with itraconazole treatment among patients with ABPA using inhaled corticosteroids, as itraconazole may cause reduced steroid clearance and/or possible direct suppression of adrenal steroid production. Interval screening for adrenal insufficiency should be considered among such persons. In contrast, the efficacy of itraconazole in ABPA may be less among persons taking agents that raise gastric pH, as this can reduce drug absorption.

Other antifungal agents, including nystatin, amphotericin B, miconazole, clotrimazole, and natamycin, are generally ineffective in controlling ABPA. Ketoconazole may be effective, but its utility is limited by hepatotoxicity. Efficacy of voriconazole has not yet been studied in ABPA, but anecdotal reports from our center and others suggest similar results to itraconazole.[61–64]

More recently, the new biologically engineered antibodies against T2 inflammatory mediators may help to control symptoms and reduce the need for systemic corticosteroids in patients with difficult-to-control ABPA. The first of these biologics directed against IgE, omalizumab, has been used successfully in ABPA but has not been studied in large randomized trials. Given that the recommended dosing of this biologic is based on patient weight and serum IgE level, many patients with ABPA are outside of the dosing range used in asthma. However, multiple case reports and small series indicate that at conventional doses (up to 375 mg subcutaneously every 2 weeks), administration may improve disease activity and spare oral corticosteroid dosing.[65–74] In addition, the biologics developed more recently against IL-4/13 (dupilumab), IL-5 (mepolizumab and reslizumab), and IL-5R (benralizumab) are being used with some anecdotal success in ABPA.[75,76]

In addition to medical therapy, all patients with ABPA-related bronchiectasis should be prescribed standard airway clearance treatments, including hypertonic saline and mucus clearance device (positive expiratory pressure device) and/or percussion vest, depending on the severity of disease. In addition, patients with ABPA should avoid areas and environmental conditions associated with high mold counts, such as decomposing organic materials and moldy indoor environments. HEPA filters may be useful if such exposures are unavoidable, but data are limited.

PROGNOSIS

With appropriate treatment, long-term control of ABPA is feasible, and durable remissions are common. Treatment of stage I disease using corticosteroids typically results in decreased sputum production, improved control of bronchospasm, >35% reduction in total IgE within 8 weeks, clearing of precipitating antibodies, and resolution of radiographic infiltrates. IgE levels typically do not completely normalize, but they generally decrease by approximately one-half of peak levels seen in the acute stage. Progression of stage IV disease to pulmonary fibrosis may be prevented if patients are maintained on low-dose steroids; most patients with stage V disease have a stable course over several years. Persons with an FEV_1 persistently <0.8 L have a worse prognosis.

In addition to severe airflow obstruction and pulmonary fibrosis, long-term complications of ABPA occasionally include the development of aspergilloma (Fig. 46-4), chronic or recurrent lobar atelectasis, allergic *Aspergillus* sinusitis, or *Aspergillus* tissue invasion and semi-invasive *Aspergillosis*. Transplantation has been undertaken successfully among patients with ABPA but should not be considered a cure, as post-transplant recurrence of ABPA has been reported.

SECTION 9 Other Obstructive Disorders

CHAPTER 47

Upper Airway Obstruction in Adults

Erin DeBiasi
Christine Won
Meir Kryger

INTRODUCTION

The upper airway is conventionally described as being made up of all the structures that conduct air between the carina and the nares and includes the trachea, larynx, pharynx, nasal airway, and oral airway. Upper airway structures may change their physiologic function in response to pressures around them and anatomic structures near them. Thus, physiologically, the segments of the upper airway behave differently when they are subject to pleural pressures (anatomically intrathoracic) or ambient pressures (anatomically extrathoracic). Furthermore, extrathoracic airway function may change with posture, sleep/wake state, and the function and anatomy of tissues surrounding the airway.

The upper airway evolved anatomically in humans to subserve several important functions including swallowing, breathing, and vocalization.[1] The multifunctionality of the upper airway increases the risk of certain diseases (e.g., aspiration and sleep apnea).[2] These functions require that different segments of the airway have differing properties. The trachea receives some support by the tracheal rings, the nasal airway is surrounded by rigid structures, and the oral airway has a rigid bony roof, the hard palate. On the other hand, the pharyngeal airway does not have rigid structures supporting it. It is a collapsible tube whose patency is maintained by muscles whose function is affected by arousal state (sleep/wake, and more specifically during sleep, the stage of sleep), the structures around it, and posture. Thus, the pharyngeal airway is divided anatomically and physiologically into the nasopharynx, retropalatal oropharynx, retroglossal oropharynx, and hypopharynx.

Clinically significant obstruction in adults may occur anywhere within the upper airway. Common etiologies of upper airway obstruction (UAO) include neoplasia, scar formation, skeletal facial malformations, infection, inflammatory disorders, trauma, extrinsic compression related to pathology of adjacent structures, and functional changes related to posture and sleep/wake state. Airway obstruction may be classified as extrinsic, intrinsic, or mixed (Fig. 47-1).

UAO can be acute and life-threatening, or chronic and resulting in significant symptoms, some of which may not even relate to the respiratory system. Initial management of acute UAO focuses on securing the airway and stabilizing the patient. Often the intervention is surgical. Some diseases require bypassing the obstruction using translaryngeal intubation or tracheostomy. Definitive long-term management depends on the underlying etiology and physiology and may include both medical and surgical interventions. The still-evolving fields of imaging and interventional pulmonology offer new diagnostic and management modalities. This chapter provides an overview of acute and chronic UAO in adults and focuses on clinical presentation, assessment, etiology, and management. Obstructive sleep apnea is covered in Chapter 98 of this volume.

CLINICAL FEATURES

Upper and lower airway obstruction may present with similar symptoms (e.g., shortness of breath, noisy breathing) and physical findings (e.g., wheezing, diminished breath sounds). Asthma and chronic obstructive pulmonary disease, common causes of lower airway obstruction, are often incorrectly assumed to be causing the patient's symptoms.

Significant UAO may be asymptomatic for a prolonged period of time, resulting in delayed presentation and diagnosis, and possibly a catastrophic outcome. When UAO develops or worsens acutely, asphyxia and death may result within minutes to hours. When UAO develops slowly, diagnoses may be delayed or incorrect and, in the case of malignancy in the upper airway, may lead to incurable disease.

Dyspnea and noisy breathing, the most common symptoms of UAO, are often prominent during exercise and may also be intensified or relieved by a change in body position. The patient may indicate that breathing is labored while supine and may experience sleep disordered breathing in the forms of obstructive sleep apnea or upper airway resistance syndrome (Chapter 98). Therefore, daytime somnolence may be a prominent feature of UAO. In severely affected patients, peripheral edema as a result of cor pulmonale may be present as a consequence of chronic hypoxemia and hypercarbia during sleep and wakefulness.

In most cases, significant anatomic obstruction precedes the development of symptoms. By the time dyspnea on exertion occurs, the airway diameter at the site of obstruction is likely to be reduced to about 8 mm. Shortness of breath at rest often develops when the airway diameter is about 5 mm, and stridor is now often present. Although airway radius does play a significant role in symptom development, it is important to note that other factors such as length of stenosis and pressure differential across the stenosis also influence perceived symptoms. Stridor is a loud, musical sound of constant pitch that usually indicates the presence of extrathoracic airway obstruction most often affecting the larynx or upper trachea.

Unlike wheezing, which is a feature of diffuse peripheral airway obstruction and occurs primarily during expiration, stridor usually occurs during inspiration and is loudest in the neck. The sound can usually be appreciated without using a stethoscope. Although one would expect to be able to distinguish stridor from wheezing coming from lower airways, sound recordings from the neck and chest have shown that the sounds from the asthmatic wheeze and stridor have similar frequencies.

Breathing maneuvers that increase inspiratory airflow, such as forced inspiration or voluntary hyperventilation, accentuate the intensity of stridor. Neck flexion may change the loudness of stridor. When the obstructing lesion is fixed, both inspiratory and expiratory stridorous sounds may be heard. At times, the character of a patient's voice may be a clue to the presence of UAO. Hoarseness may be a sign of a laryngeal abnormality. Muffling of the voice may be present when vocal cords are paralyzed.

LABORATORY ASSESSMENT

Just as UAO must be quite advanced before development of symptoms, physiologic abnormalities do not become apparent on lung function testing until severe obstruction (<8 mm or 80% of normal medial tracheal diameter) occurs. The forced expiratory volume in 1 s (FEV$_1$) remains above 90% of control until a 6-mm orifice is created. Therefore, spirometry may not be an effective way to detect upper airway abnormalities. The peak expiratory flow rate (PEFR) and maximal voluntary ventilation (MVV) are more sensitive than the FEV$_1$ in detecting UAO. Of note, a noncritical airway may become so with a lesser degree of obstruction in the context of airway secretions, edema, or bleeding.[9]

The flow–volume loop, which is a recording of maximal inspiratory and expiratory flows at various lung volumes, is an important tool for the diagnosis of UAO. The configuration of the normal flow–volume loop is shown in Fig. 47-2. During a forced expiratory maneuver from total lung capacity (TLC), the maximal flow achieved during the first 25% of the forced vital capacity is dependent on effort—that is, an increase in driving pressure (effort) may result in increased flow. During the remaining 75% of the forced vital capacity maneuver, flow is determined by the mechanical properties of the lungs and is not effort dependent. During this portion of forced exhalation, a linear deceleration of flow is caused by dynamic compression of the intrathoracic airways (Fig. 47-3A). An increase in effort and therefore pleural pressure causes further compression of the intrathoracic airways and a further limitation of airflow. At higher lung volumes, flow may be limited by a UAO. At low lung volumes, flow may not be affected by a UAO, since measurement of flow in this effort-independent portion of the curve represents the function of the peripheral airways. Since the FEV$_1$ reflects a large portion of flow at these lower lung volumes, it is not a sensitive test for UAO. Because the PEFR reflects flow at higher lung volumes, it may be abnormal when the FEV$_1$ is not.

In generating the flow–volume loop, forced inspiratory flow is limited by effort during the entire inspiratory maneuver. Flow increases from residual volume to near the midportion of the curve, where it becomes maximal at the peak inspiratory flow rate. Flow then declines until TLC is reached. The pressure surrounding the extrathoracic portion of the upper airway is atmospheric. The turbulent nonlaminar airflow, which occurs during forced inspiration and causes airway pressure to fall in this portion of the airway, favors slight narrowing of the extrathoracic airway (Fig. 47-3A, B). Peak inspiratory flow, therefore, is less than peak expiratory flow in normal subjects. Because of the dynamic compression of the intrathoracic airways that occurs during exhalation, flow during the middle of inspiration, that is, the forced inspiratory flow at 50% of the forced vital capacity (FIF$_{50\%}$), is usually greater than flow during the middle of forced expiration, that is, the forced expiratory flow at 50% of the forced vital capacity (FEF$_{50\%}$). Typical patterns of the flow–volume loop may be seen, depending on whether the obstruction to flow is "fixed" or "variable," and whether the site of the obstruction is above or below the thoracic outlet or suprasternal notch.

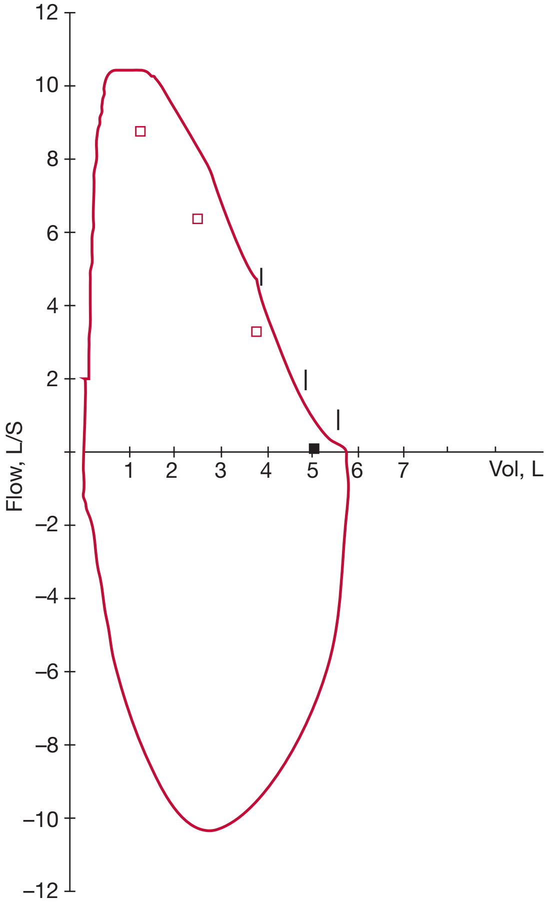

Figure 47-2 Normal flow–volume loop following maximal expiratory *(above)* and inspiratory *(below)* effort. Small vertical lines denote seconds.

Fixed obstructions of the upper airway are those in which the cross-sectional area does not change in response to transmural pressure differences during inspiration or expiration. A fixed obstruction may occur in either the intrathoracic or extrathoracic airways. Irrespective of the site of the obstruction, a fixed lesion results in the flattening of the inspiratory and expiratory phases of the flow–volume loop. A *variable obstruction* is one that responds to transmural pressure changes, eliciting varying degrees of obstruction during the respiratory cycle. Since the stresses on the intrathoracic and extrathoracic airways are different, changes seen in the flow–volume loop vary according to the site of the obstruction.

A number of conditions have been associated with nondistensible narrowing of the upper airway and fixed airway obstruction. Benign strictures and malignancy are common examples. Maximal inspiratory and expiratory flow–volume loops with fixed obstruction show constant flow, represented by a plateau during both inspiration and

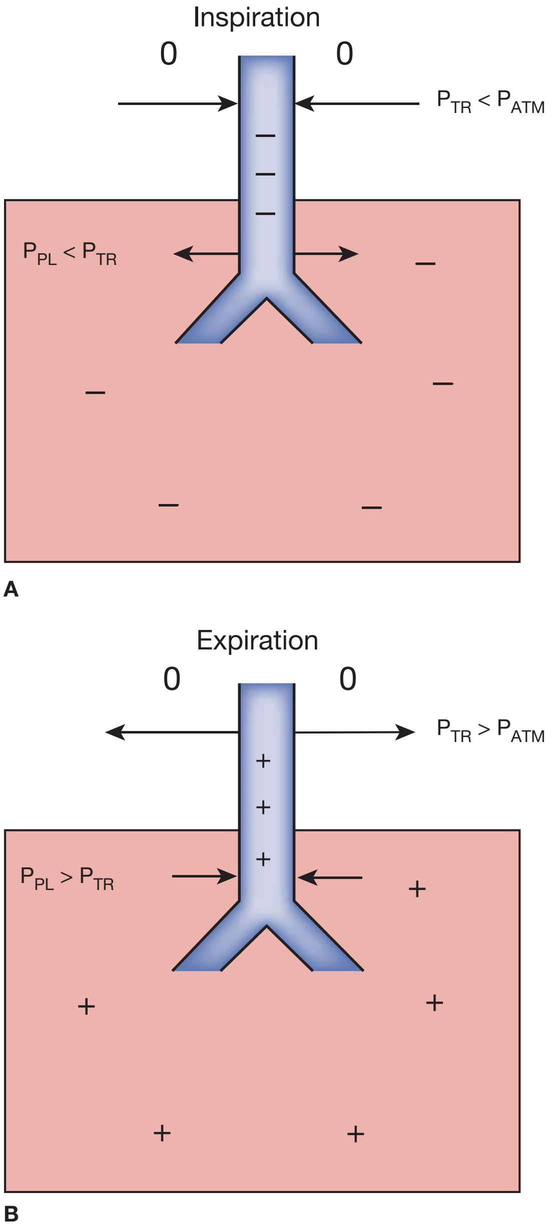

Figure 47-3 Forces acting on intra- and extrathoracic airway walls during inspiration and expiration. 0, atmospheric pressure; +, positive pressure; −, negative pressure. **A.** During inspiration, extrathoracic tracheal pressure (P_{TR}) falls below atmospheric pressure (P_{ATM}), favoring narrowing of the lumen *(arrows)*. Intrapleural pressure (P_{PL}) becomes negative, favoring airway enlargement *(arrows)*. **B.** During expiration, the extrathoracic tracheal pressure (P_{TR}) becomes positive and, therefore, greater than P_{ATM}, favoring enlargement of the lumen *(arrows)*. Intrapleural pressure (P_{PL}) is positive, causing dynamic compression of the intrathoracic trachea *(arrows)*.

expiration (Fig. 47-4A, B). On the expiratory curve, the plateau effect is seen in the effort-dependent portion of the curve near TLC; very little change is noted in the effort-dependent portion near residual volume. Since the inspiratory curve is similar in appearance, the ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is normal (close to 1). The forced inspiratory volume in 1 second (FIV_1) and FEV_1 are nearly the same in fixed UAO.

Unilateral vocal cord paralysis is a common cause of variable extrathoracic obstruction. A variable extrathoracic airway obstruction increases the turbulence of inspiratory flow, and intraluminal pressure falls markedly below atmospheric pressure. This leads to partial collapse of an already narrowed airway and a plateau in the inspiratory flow loop (Fig. 47-5A, B). Expiratory flow is not significantly affected, since the markedly positive pressure in the airway tends to decrease the obstruction. The ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is high (usually >2). Similarly, the FEV_1 is greater than the FIV_1.

A variable obstruction in the intrathoracic airways reverses the situation. A predominant reduction in maximal expiratory flow is associated with a relative preservation of maximal inspiratory flow. This association occurs because intrapleural pressure becomes decidedly positive during forced expiration and causes dynamic compression of the intrathoracic airways. The obstruction caused by an intrathoracic lesion is accentuated, and a plateau in expiratory flow occurs on the flow–volume loop (Fig. 47-6A, B). A plateau of flow suggests that the lesion has caused the airway lumen to reach its minimal size. A flow peak may precede the plateau, suggesting that the obstruction may not affect flow until a certain lung volume is reached. During inspiration, intrapleural pressure is markedly negative; therefore, the obstruction is decreased. The ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is very low and may approach 0.3. Similarly, the FEV_1 is considerably lower than the FIV_1. Although the flow ratios are similar to those seen in patients with COPD and chronic asthma, these disorders are distinguished from UAO by the appearance of the flow–volume loop. Thus, the expiratory curve in patients with COPD and asthma is primarily altered in the effort-independent portion of the curve, leading to a characteristic shape unlike the plateau configuration of a UAO (Fig. 47-7).

When a hospital laboratory or physician's office is not equipped to perform flow–volume loops, results of other tests, such as routine spirometry, may be helpful. If the forced spirogram shows that the PEFR is reduced disproportionately to the reduction in FEV_1, a UAO should be suspected. Other findings that suggest the diagnosis include a ratio of less than 1.0 for the inspiratory flow between 25% and 75% of the inspired vital capacity ($FIF_{25–75\%}$) and a value of less than 1.0 for the expiratory flow between 25% and 75% of the expired vital capacity ($FEF_{25–75\%}$). Another indication is an FEV_1 that is decreased to the same degree as the $FEF_{25–75\%}$. The MVV also may be a useful test, since it measures both inspiratory and expiratory flows. A ratio of MVV to FEV_1 of less than 25% is often found with UAO. Whenever the MVV is reduced in association with a normal FEV_1, a diagnosis of UAO should be considered.

In contrast to the situation in patients with diffuse obstructive disease of the lower airways (e.g., COPD, asthma), the distribution of ventilation in the lungs is normal, and ventilation–perfusion mismatch does not occur. Hypercarbia is not seen unless the degree of obstruction is very severe, although nocturnal hypercarbia may occur while daytime levels of P_{CO_2} are normal. Hypoxemia is also not present except during exercise and with severe airflow limitation, when it may accompany increases in the level of P_{CO_2}. In contrast to asthma and many instances of COPD, the airflow obstruction caused by an upper airway lesion does not resolve following the inhalation of a bronchodilator unless there is also a component of small airway disease that is often the case.

IMAGING

When acute airflow obstruction occurs as a result of an abnormality of the extrathoracic airway, roentgenographic studies of the soft tissues of the upper chest and neck in the emergency setting may be helpful (Fig. 47-8). However, computed tomography (CT) has afforded the most important approach to imaging of the extrathoracic airways (Fig. 47-9). The standard chest roentgenogram is often not helpful in detecting UAO. The trachea is usually well visualized on the posteroanterior (PA) and lateral views in chest

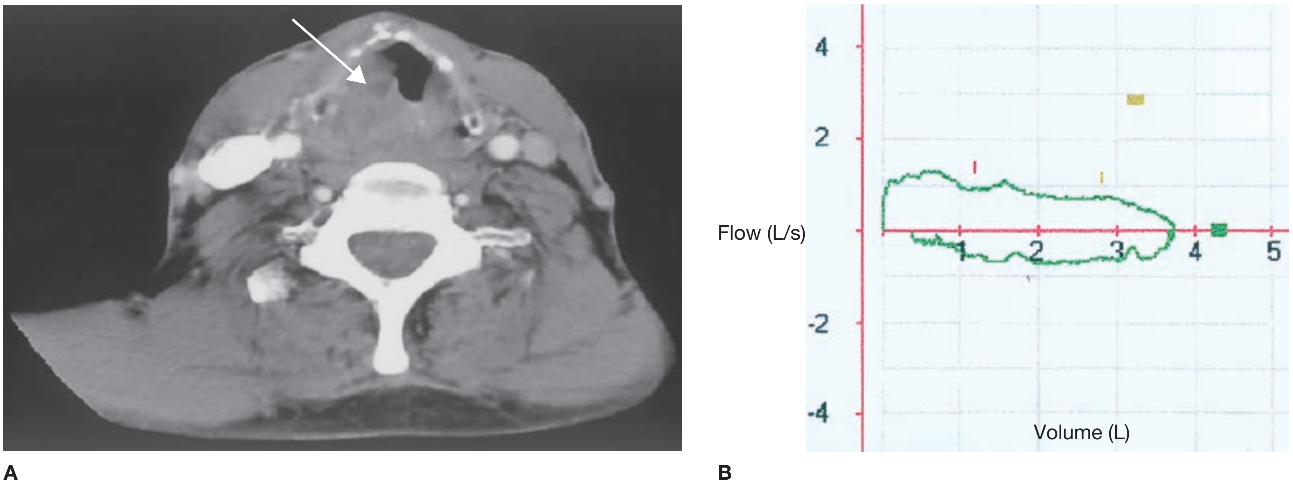

Figure 47-4 **A, B.** Flow–volume loop in fixed upper airway obstruction due to laryngeal abscess in a 56-year-old man who developed persistent wheezing, hoarseness of voice, and intermittent stridor for 3 months after a brief intubation for asthma exacerbation. Computed tomography scan of the neck (**A**) shows a laryngeal abscess with significant impingement on the laryngeal inlet. The flow–volume loop (**B**) demonstrates a plateau of flow during inspiration and expiration; the $FEF_{50\%}/FIF_{50\%}$ ratio is near 1.

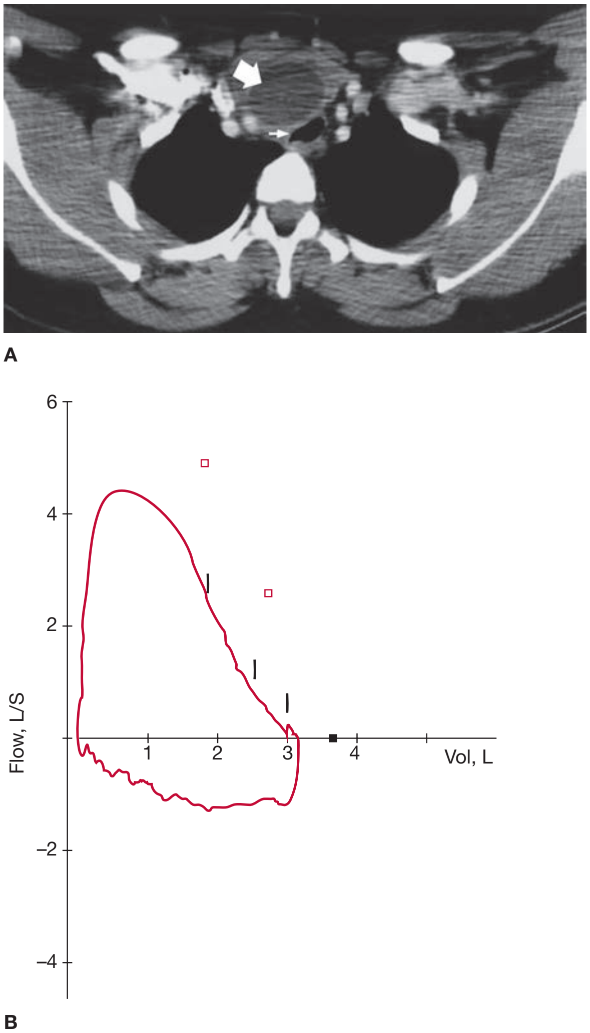

Figure 47-5 Variable extrathoracic obstruction due to thyroid cyst in a 32-year-old woman with dyspnea on exertion. **A.** Computed tomography of the neck shows a 10- × 4-cm cystic mass *(large arrow)* in the thyroid gland compressing the trachea *(small arrow)*. **B.** Flow–volume loop shows inspiratory obstruction. $FEF_{50\%}/FIF_{50\%}$ is very high, and the inspiratory curve is flattened.

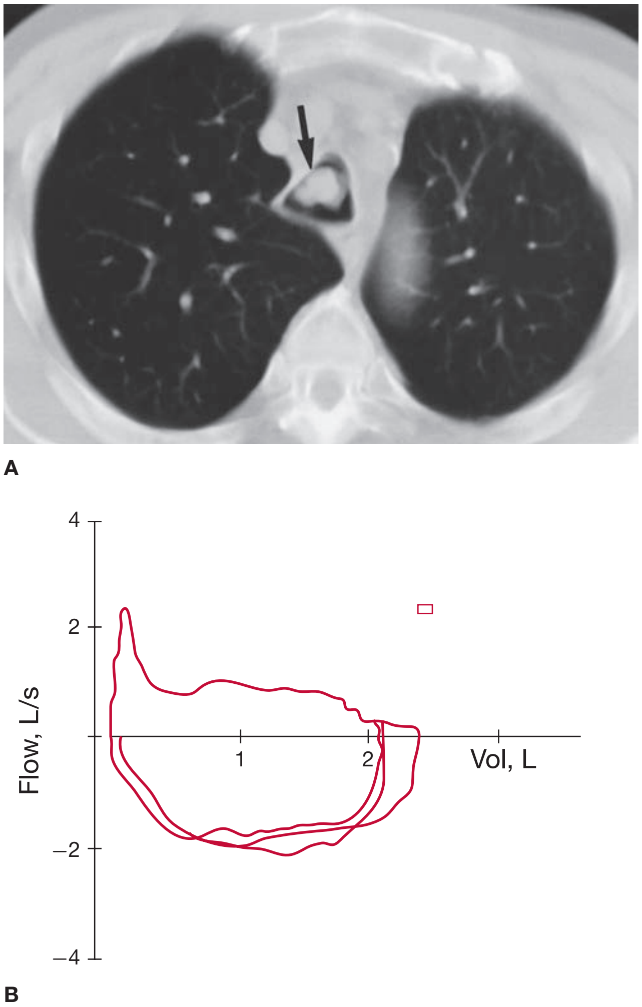

Figure 47-6 Variable intrathoracic obstruction due to squamous cell carcinoma of the trachea. **A.** Computed tomography of the chest shows a tracheal lesion *(arrow)*, which was not readily apparent on plain chest radiograph. **B.** Superimposed flow–volume loops show a plateau of expiratory flow preceded by a peak of flow at higher lung volumes. The forced inspiratory flow is preserved in comparison to expiratory flow, but it is also reduced. $FEF_{50\%}/FIF_{50\%}$ is 0.4.

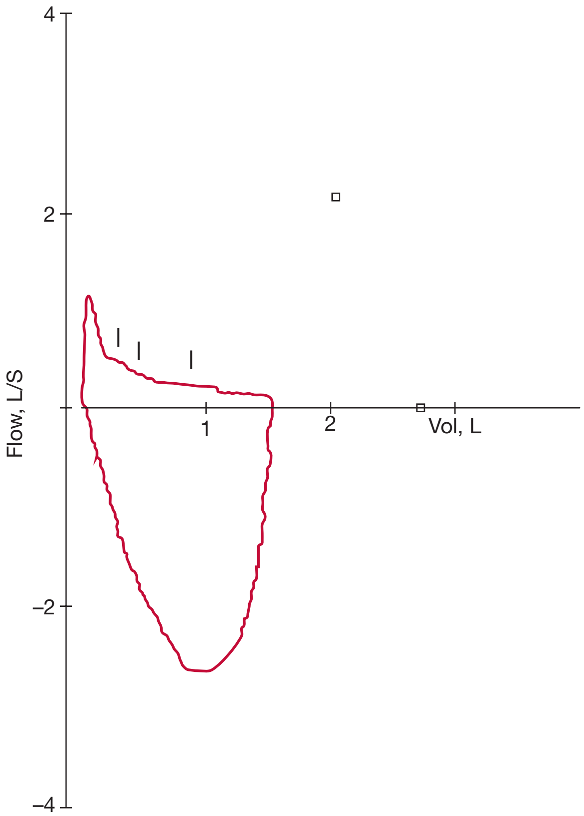

Figure 47-7 Flow–volume loop typical of chronic obstructive lung disease. Very low $FEF_{50\%}/FIF_{50\%}$ and typical curvilinear shape are noted.

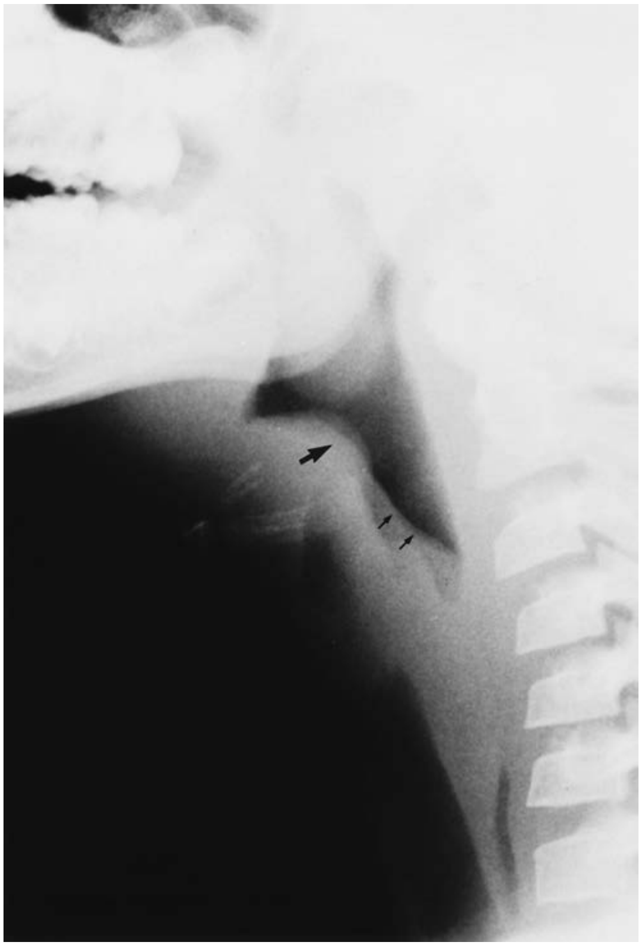

Figure 47-8 Acute epiglottitis. Lateral soft tissue radiograph of the neck of a patient with stridor shows swelling of the epiglottis *(large arrow)* and loss of normal convexity of the edematous aryepiglottic folds *(small arrows)*.

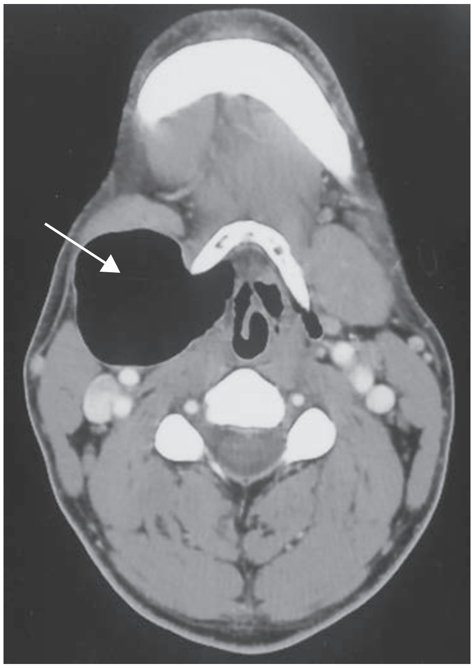

Figure 47-9 Computed tomography scan of the neck demonstrating a large laryngocele compressing the lateral wall of the larynx *(arrow)* causing positional air flow obstruction.

roentgenograms of good quality. It is located in the midline and is moderately deviated at the level of the aortic arch. However, many standard roentgenograms are underpenetrated so that the trachea may become a "blind spot." In one study, only 13 of 53 tracheal tumors were evident to the radiologist on the standard PA roentgenogram. A lateral roentgenogram can provide a less obscured image of a tracheal abnormality, especially when the posterior wall is involved. Thoracic CT studies have become the procedure of choice for imaging the upper airway.

Helical CT (HCT) scanning minimizes artifacts due to respiratory motion and provides imaging of the whole thoracic volume during a single breathhold.[10] The technique represents an improvement over conventional CT scanning in that it allows detection of intraluminal, submucosal, and extraluminal lesions (Figs. 47-10A, B and 47-11). Since the early 1990s, HCT has become the preferred noninvasive modality for evaluation of the central airways. The use of HCT using multidetector technology and thin collimation provides high-resolution images of the entire thorax, improved special resolution, greater speed of image acquisition, and excellent contrast enhancement. HCT techniques using multiplanar and three-dimensional reconstruction can provide virtual images of the thorax that enhance the perception of local and diffuse anatomic lesions of the upper airways (Fig. 47-12). The images may demonstrate the degree of tracheal widening or narrowing, show the location and longitudinal extent of abnormalities, assess tracheal wall thickness, and demonstrate associated extratracheal diseases.

The use of paired inspiratory dynamic and expiratory multislice HCT has proved helpful for the diagnosis of tracheomalacia. Because the maximal degree of collapse in tracheomalacia usually occurs during exhalation rather than at end expiration, dynamic expiratory imaging is preferable to end-expiratory imaging. If complete collapse is not demonstrated during expiration, then

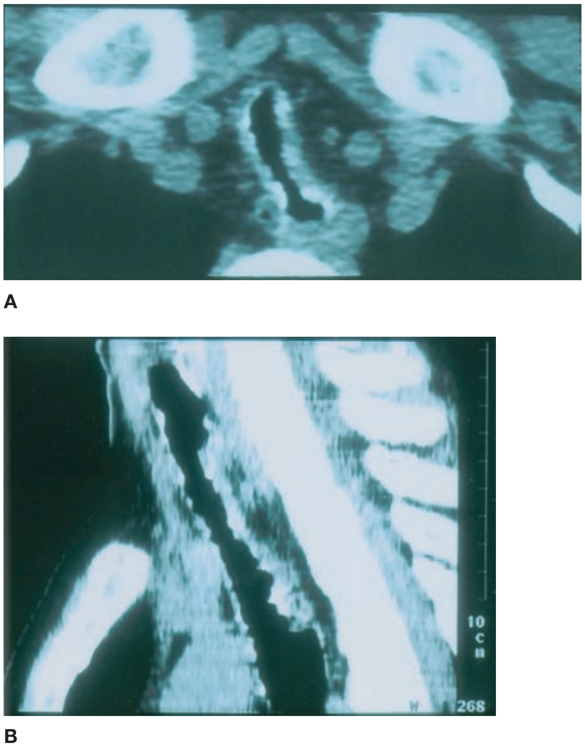

Figure 47-10 **A.** Computed tomography scan of the chest demonstrating marked narrowing of the trachea with intraluminal calcified nodular projections in a patient with tracheopathia osteoplastica. **B.** Computed tomography scan of the chest demonstrating multiplanar reformation of the trachea in the sagittal plane of the same patient.

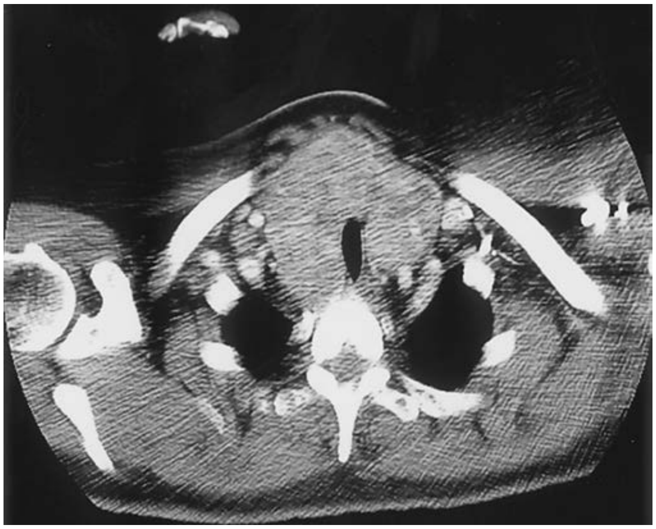

Figure 47-11 Computed tomography scan of the chest demonstrating marked extraluminal compression of the trachea caused by intrathoracic goiter.

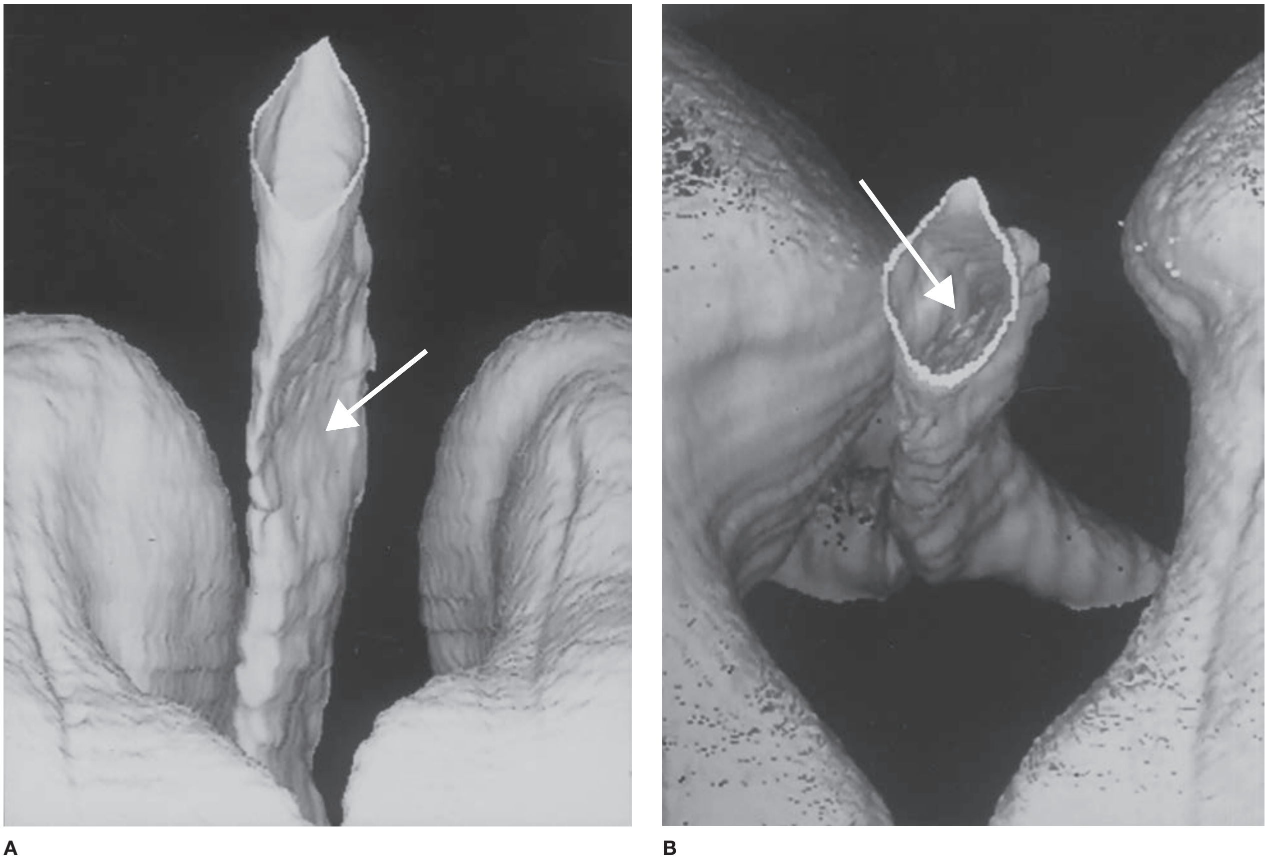

Figure 47-12 Helical computed tomography scan of the chest with three-dimensional reconstruction of the upper airway showing focal tracheal compression *(arrows)* (**A, B**).

one should confirm the diagnosis by quantitatively measuring the degree of airway luminal narrowing during expiration.

Another novel CT-based imaging technique is virtual bronchoscopy. The use of volumetric imaging allows for an intraluminal three-dimensional reconstruction of the airways and surrounding tissues. The technique has been used with a high degree of accuracy in assessing the width, length, and contour of fixed airway lesions.

Magnetic resonance imaging (MRI) provides a multiplane image of the chest without the need for contrast material. It is best used to investigate vascular structures surrounding central airways rather than the airways themselves, which are better visualized using CT scanning.

ENDOSCOPY

Bronchoscopy and direct laryngoscopy provide a real-time morphologic and functional evaluation of the upper airway. Imaging techniques are often limited by their inability to document the dynamic nature of many airway lesions and may underestimate the extent of an obstruction. With respect to laryngeal disease, endoscopy allows the operator to determine whether the vocal cords are mobile or fixed in abduction or adduction or alternatively moving paradoxically. This valuable information can help guide management. In cases of traumatic or thermal injury to the airways, edema, laryngeal fracture, or carbonaceous materials can be readily identified.

CLASSIFICATION

Stenosis classification systems are an objective tool that can be used between clinicians to provide an accurate characterization of the stenosis. While several classification systems exist for upper airway obstruction and none is universally accepted, broadly they include severity of airway narrowing, vertical length, location in the airway, cause, morphology/shape of stenosis, voice characteristics, swallowing, and functional impairment.[11]

Severity of the airway narrowing refers to the degree of reduction of cross-sectional area, with mild obstruction being less than 50% reduction in area and severe greater than 71%. Vertical length is important when considering treatment plans, as lesions >4 cm are generally considered inoperable. Location in the airway is described as relative to both the vocal cords and main carina (glottis, subglottic, tracheal, tracheobronchial). Morphology describes the shape of the airway lumen and can help determine etiology. Terms used to describe morphology include simple (short segment, concentric, <1 cm in length, and without malacia), complex (long segments >1 cm, with tracheal wall injury and/or malacia), pseudoglottic (triangular), eccentric, and circumferential. Classification of voice characteristics is on a spectrum ranging from no problems, to slight to significant impairments in audibility, to no voice. Finally, functional class is a subjective measurement of symptomatology with activities of daily living.

CAUSES OF UPPER AIRWAY OBSTRUCTION

UAO may be observed in a wide variety of settings, including infections, trauma (including iatrogenic), vascular disorders, and a wide variety of benign and malignant tumors. Each is discussed below.

■ Infection

A broad variety of infections may eventuate in UAO.

Deep Cervical Space Infections

Deep cervical space infections occur in potential spaces bounded by the deep cervical fascia. Patients with deep cervical space infections may present with sore throat, odynophagia, neck swelling, pain, fever, and dyspnea. Stridor and profound respiratory difficulty are signs of significant UAO. Parapharyngeal, peritonsillar, submandibular, and retropharyngeal abscesses appear to be common locations in adults. The bacteriology and initiating event of deep cervical infections appear to have changed over time.

Mixed infections caused by aerobic and anaerobic infections are common and have been reported in up to two-thirds of cases.[12] *Streptococcus viridans* and *Klebsiella pneumonia* are common pathogens. *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, *Escherichia coli*, and *Haemophilus influenzae* are other agents that are commonly reported. Alpha- and beta-hemolytic *streptococci* appear to have significantly declined in frequency. Overall, an odontogenic origin is probably most common. Intravenous drug abuse, mandibular fractures, iatrogenic and noniatrogenic traumatic injury to the upper airway, underlying malignancy, and poor underlying immune status are associated conditions. Ludwig's angina—an infection of the submandibular space and the floor of the mouth—is potentially lethal and is commonly associated with significant UAO. This entity is usually a cellulitic process and can affect the submandibular spaces bilaterally. Conservative management with antibiotics leads to significantly higher incidence of airway compromise compared with surgical drainage.[13] Many cases with true Ludwig's angina require tracheostomy.

Treatment of deep cervical infections involves maintenance of oxygenation and ventilation by securing an adequate airway, administration of appropriate antibiotics, and when indicated, use of surgical drainage. Complications of deep cervical infections include UAO, Lemierre's syndrome (see next paragraph), distant infection, septic embolization, carotid artery rupture, pulmonary embolism, direct extension of infection resulting in mediastinitis and empyema, and rupture of the abscess during intubation or other interventions.[14]

One particularly virulent cervical infection, known as Lemierre's syndrome, arises from a nasopharyngitis or peritonsillar abscess commonly due to *Fusobacterium necrophorum.* This lateral pharyngeal space infection results in suppurative thrombophlebitis of the internal jugular vein, septicemia, and metastatic abscess formation, particularly in the lungs and joints. Symptoms begin with a sore throat, fever, and painful swelling in the neck, followed by tender lymphadenopathy and tenderness along the sternocleidomastoid muscle due to thrombophlebitis of the internal jugular vein. Dysphagia, trismus, and UAO may occur as a result of swelling of the lateral pharyngeal space. Contrast-enhanced CT scan of the neck demonstrates thrombosis of the internal jugular vein, soft tissue abscesses, fasciitis, and myositis. Treatment with prompt antibiotics, such as high-dose penicillin with metronidazole, or monotherapy with clindamycin is key has led to the recent mortality rate of 5%.[15]

Epiglottitis

Epiglottitis is an infectious process that causes variable degrees of inflammation and edema of the epiglottis and supraglottic structures. Supraglottic structures usually are involved with variable involvement of the epiglottis in adults. Clinical presentation includes odynophagia, with inability to swallow secretions, sore throat, dyspnea, hoarseness, fever, tachycardia, and stridor. In one review, 44% of the patients had a normal routine oropharyngeal examination.[16]

Fiberoptic laryngoscopy is necessary to make the diagnosis and should be done without delay. Radiographic studies can be helpful in ruling out other etiologies with similar presentations and in evaluating potential complications but should not delay diagnosis or management.

Supraglottitis may involve the base of the tongue, uvula, pharynx, and false vocal cords. The disease may be increasing in prevalence among adults and declining in children, perhaps reflecting introduction of *Haemophilus b* conjugate vaccines. Young adult males are commonly affected. The disorder appears to be more prevalent in colder winter months and in smokers. Blood cultures are positive in less than one-third of cases. Adult supraglottitis may be caused by a variety of organisms, including *Haemophilus influenzae*, pneumococci, group A streptococci, *S. aureus*, *Streptococcus viridans*, a variety of anaerobic organisms, mycobacteria, fungi, and viruses. Throat cultures can be helpful in diagnosis and management; however, treatment should not be delayed while awaiting culture results.

Illicit drug use may be associated with epiglottitis, with inhalation of heated objects (e.g., metal pieces from a crack cocaine pipe or the tip of a marijuana cigarette) causing thermal injury to supraglottic structures. Signs, symptoms, and roentgenographic and laryngoscopic findings are similar to those of infectious epiglottitis.

Initial antibiotic therapy using a third-generation cephalosporin or extended-spectrum penicillin is reasonable. The prevalence of resistant organisms should be considered when choosing empiric antibiotic coverage. Corticosteroids often are used in management of acute epiglottitis despite lack of evidence to support their use. Based on anecdotal case reports, epinephrine also is used.

Patients should be observed closely, and experienced staff should be available immediately to secure the airway by intubation or surgical approach, if needed. In a recent study, up to 10% of patients required ICU admission, and 4.4% required airway intervention.[17] Elevated blood glucose levels and CRP as well as a relative neutropenia predicted the need for higher level of care. Males were more likely to have recurrent disease, which was associated with an increased need for airway intervention. Securing the airway is extremely important in patients who develop stridor and other signs of significant airway obstruction. Mortality is around 2% to 3% but can be significantly higher, up to 17.6%, in those who require airway intervention.[18]

Laryngotracheobronchitis and Bacterial Tracheitis

Laryngotracheobronchitis, often called croup, is commonly seen in children who present with hoarseness, barking cough, shortness of breath, and stridor. This is an acute viral illness characterized by narrowing of the subglottic area. Adult croup is a rare condition. Rare instances of diphtheritic croup have been described in adults. Noninfectious membranous tracheitis related to trauma also has been reported.

Acute bacterial tracheitis refers to involvement of the subglottic trachea by bacterial infection and usually follows an episode of viral laryngotracheobronchitis. Thick, purulent exudates and mucosal edema may cause symptoms of UAO. *S. aureus* appears to be the predominant organism. Prompt antibiotic therapy, close observation with attention to airway compromise, and frequent suctioning are important. Data to suggest effectiveness of steroids or epinephrine in adults are lacking.

Rhinoscleroma is a chronic, progressive granulomatous infection of the upper airway that may cause airflow obstruction. This disorder affects primarily the nose and paranasal sinuses, but also may involve the nasopharynx, larynx, trachea, and bronchi. The causative organism is *Klebsiella rhinoscleromatis*. Rhinoscleroma is endemic in Africa, Asia, and South America and is rare in North America. About 5% of patients have diffuse narrowing of the trachea.[19] Prolonged antibiotic therapy with trimethoprim/sulfamethoxazole is effective.

Tuberculosis

Involvement of the upper airway can be observed both with and without pulmonary disease. Primary disease can develop due to direct inoculation of the airway with acid-fast bacilli, whereas secondary disease is due to either direct spread from advanced pulmonary disease or hematogenous or lymphatic seeding. Laryngeal tuberculosis is relatively uncommon, accounting for less than 1% of tuberculosis cases. The true vocal cords and epiglottis are the areas most affected. Laryngeal tuberculosis may present as progressive hoarseness and ulceration or a laryngeal mass. Endobronchial tuberculosis can be seen throughout the tracheobronchial tree and may result in significant airflow limitation that is related to the initial lesion or subsequent stricture formation. A barking cough and sputum production are common findings. In the appropriate clinical context, a positive purified protein derivative (PPD) skin test and acid-fast bacilli in sputum may suggest the diagnosis. However, a biopsy from the laryngeal or endobronchial abnormality usually is required. Biopsy features include caseating granulomas and acid-fast bacilli. Treatment with antituberculous medications is usually adequate and should be instituted promptly, since the disease is highly contagious. Additionally, prompt treatment with antituberculous medications should decrease the development of endobronchial fibrostenosis and resultant airflow limitation. Surgical interventions, including tracheostomy, are reserved for airway obstruction and long-term complications and, in one report, were required in 12% of patients with laryngeal involevement.[20]

■ Upper Airway Tumors

Both head and neck cancers and tracheal tumors may cause UAO.

Head and Neck Cancer

The great majority of cancers that impact the upper airway are squamous cell carcinomas, and the incidence of oropharyngeal cancer appears to be increasing in some countries (Fig. 47-13).[21] Other less common cancers occurring in the oropharynx include salivary gland carcinomas, lymphomas, and lymphoepitheliomas. Tobacco, alcohol abuse, and infection with human papillomavirus (HPV), especially HPV type 16, are the most common risk factors for the development of head and neck cancers.[22–24] The incidence of head and neck cancer is declining in the Unites States, concurrent with a reduction in tobacco use, accounting for about 3% of all malignancies.[25]

The clinical manifestations of head and neck cancer depend on the location and stage. Cancers at the base of the tongue and pharyngeal walls are insidious. These cancers grow in an infiltrative or exophytic pattern. Because of the lack of pain fibers at the base of the tongue, these tumors are often asymptomatic until they are far advanced. The most common location of a primary tumor of the

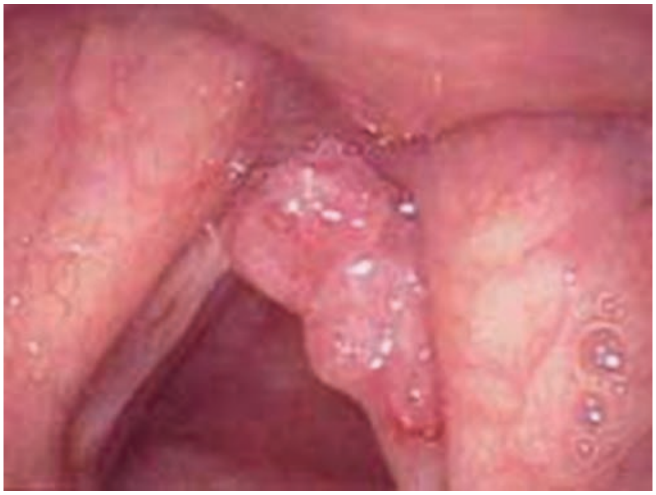

Figure 47-13 Laryngeal squamous cell carcinoma.

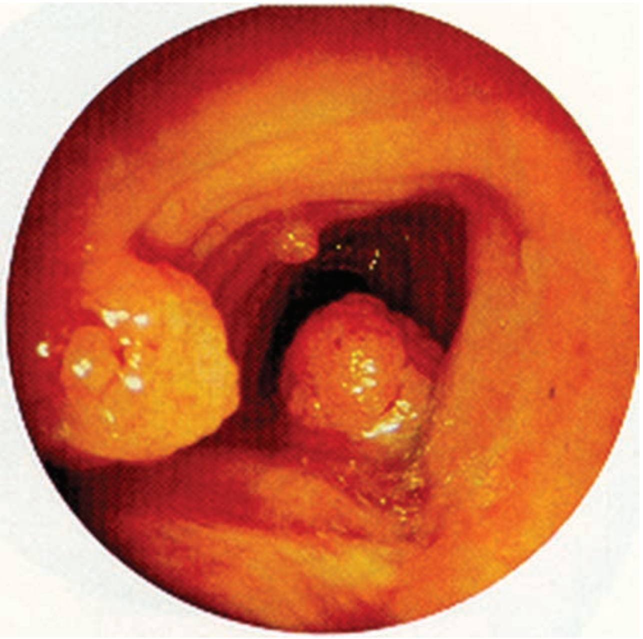

Figure 47-14 Squamous cell carcinoma of the lung.

oropharynx is the anterior tonsillar pillar or tonsil. Symptoms of these cancers include hoarseness, hemoptysis, sore throat, dysphagia, referred otalgia due to cranial nerve involvement, and trismus due to pterygoid muscle involvement. Life-threatening UAO may be seen. Patients who have had head and neck surgery for cancer have a very high prevalence of obstructive sleep apnea.

Tracheal Cancer

Tumors that originate in the trachea are uncommon and make up only about 2% of all tumors that form in the upper airway. Although rare, when they do occur, approximately 80% of tracheal tumors are malignant. Primary tracheal cancers are rare, with a reported incidence of 0.1 per 100,000 per year.[26] Dyspnea, cough, wheeze, and stridor are frequent presenting symptoms. Squamous cell carcinoma (SCC) is the predominant histology (45%), followed by adenoid cystic carcinoma (ACC) (16%).[27] SCC is almost always associated with cigarette smoking. These tumors grow quickly, and in nearly half of cases they are too large to be removed by the time they are discovered. Hemoptysis is often another presenting symptom. ACC grows much more slowly and has not been found to be related to smoking. Men and women have the same risk for this type of cancer, and it is commonly diagnosed around the age of 40 years. Hemoptysis is an uncommon presentation for ACC. Surgery remains the most effective management. Emergency treatment with procedures to recanalize the airway, including airway stenting, may be necessary pending definitive surgery. Postoperative radiation therapy appears useful for primary tracheal malignancies, particularly when surgical margins are positive. Palliative radiation is used for local control when surgery is contraindicated. Five-year survival is highly dependent on resectability. For resectable adenoid cystic and squamous cell carcinomas, survival rates are reported at 52% and 39%, respectively, whereas in unresectable disease these rates are 39% and 7%, respectively.[28] Late recurrence of ACC is possible due to early perineural infiltration. Favorable prognostic factors include negative airway margins at the time of resection and adenoid cystic histology.

More commonly, malignancies found in the trachea result from direct extension of primary lung cancer or regional extension to the lymph nodes (Fig. 47-14). Metastases to central airways from nonpulmonary malignancies are uncommon, although endobronchial metastases from breast, colorectal, renal, ovarian, thyroid, uterine, testicular, nasopharyngeal, and adrenal carcinomas, as well as sarcomas, melanomas, and plasmacytomas have been described. In an autopsy series of more than 1300 patients with solid tumors, metastatic disease to central airways occurred in 2%.[29] The mediastinal lymph nodes are also a common site for disease involvement from hematologic malignancies such as lymphoma.

Nonmalignant tracheal tumors include papillomas, chondromas, and hemangiomas (Fig. 47-15). Chondromas are the most common

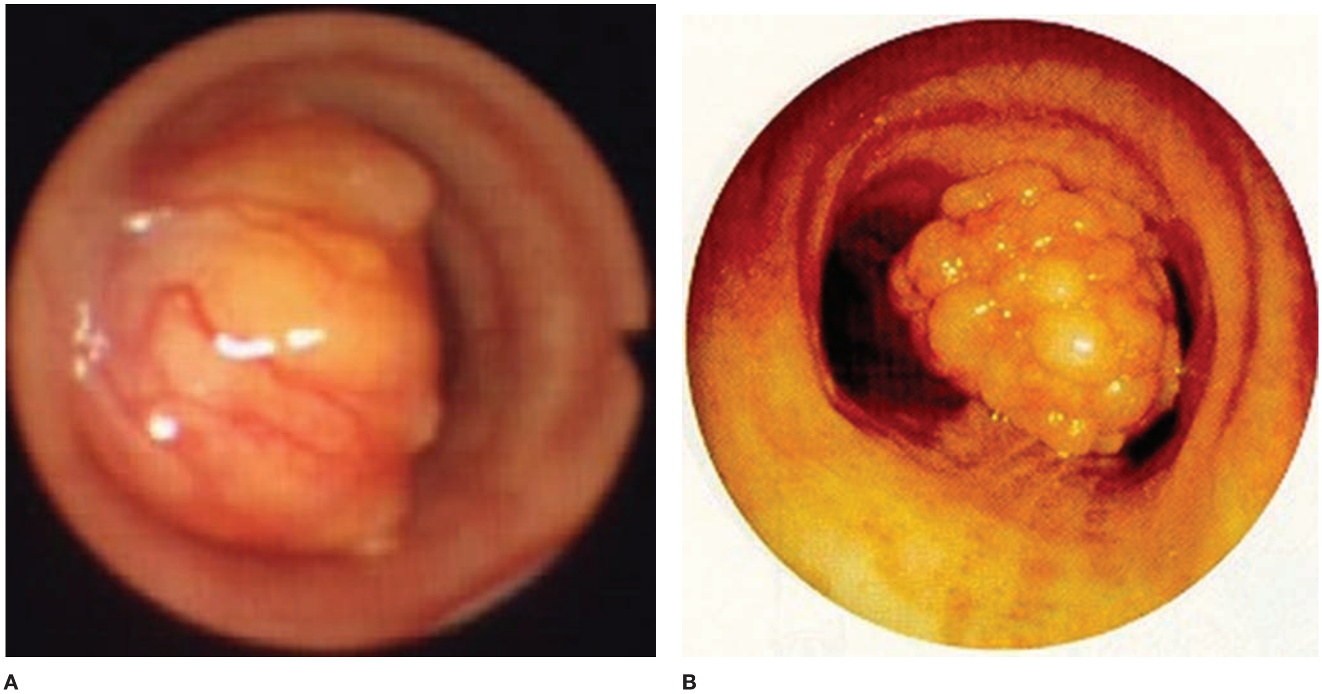

Figure 47-15 Nonmalignant tracheal tumors. **A.** Hamartoma. **B.** Papillomatosis.

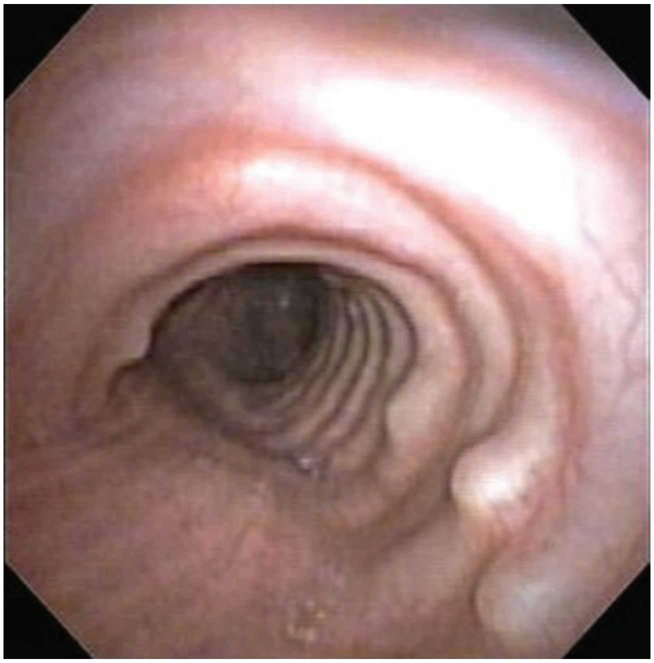

Figure 47-15 *(Continued)* **C.** Chondromas.

type of benign tracheal tumor. They are formed from the cartilage rings of the trachea and have the potential to become malignant over time. Recurrent respiratory papillomatosis in adults, caused by human papillomavirus types 6 or 11 (or, much less commonly, types 16 or 18) may result in UAO and death. Although the larynx is most commonly affected (Fig. 47-16), the tracheobronchial tree may be involved, with a predilection toward areas with prior mucosal injury, including tracheostomy sites and tracheal injuries. Lesions tend to progress down through the tracheobronchial tree. Pulmonary parenchymal involvement is rare, but it may be severe, and bronchiectasis, pulmonary nodules, and abscess formation may occur. Malignant transformation also is possible. The course of the disease is difficult to predict. Recurrent endoscopic interventions (debulking), with attendant risk of airway stenosis, are often required. It is important to minimize intervention unless clinically relevant obstruction exists due to concerns regarding extension secondary to airway injury. No controlled trials on the role of antiviral therapy have been conducted. Available data suggest beneficial effects of intralesional cidofovir, and it is recommended to treat with cidofovir when debulking is required at least every 2 to 3 months.[30] Bevacizumab also has been shown to have benefit when used in combination with debulking.[31] Favorable effects also have been reported with the use of interferon alpha, although the agent is not often used due to systemic side effects. Chemotherapy, radiation therapy, and targeted surgical resection are utilized for confirmed malignant transformation. The HPV vaccine Gardasil has shown promising results for secondary prevention of RPP as well as disease control.[32]

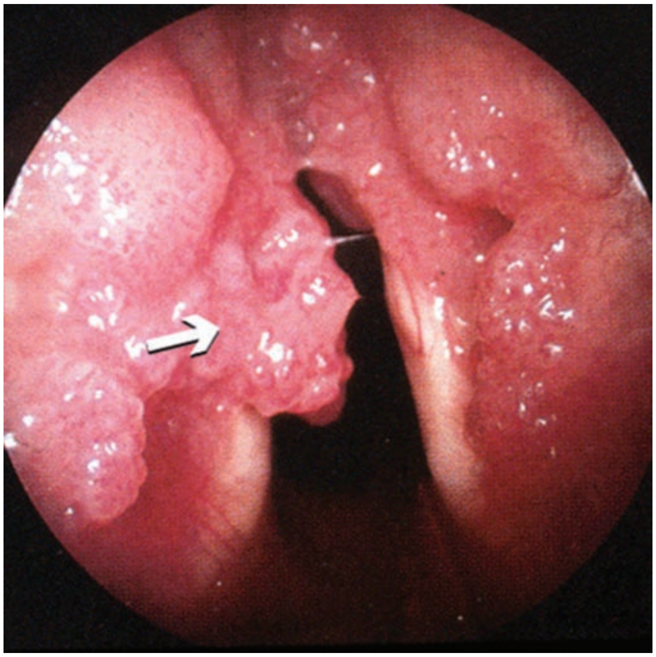

Figure 47-16 Recurrent laryngeal papillomatosis *(arrow)*.

■ Laryngeal and Tracheal Stenosis

Common causes of laryngeal and tracheal stenosis include prior intubation and tracheotomy. However, many other causes have been reported.

Postintubation and Posttracheotomy Stenosis (PITS and PTTS)

Endotracheal intubation, tracheostomy, and prior laryngotracheal instrumentation account for most cases of laryngotracheal stenosis. The reported frequencies of tracheal stenosis following tracheostomy or laryngotracheal intubation vary widely, but recent large retrospective studies suggest that the incidence of clinically significant stenosis is low (0%–1.8%) (Figs. 47-17 and 47-18).[33,34] Patient demographics associated with an increased incidence of PITS/PTTS include female sex (75%), obesity (66%), diabetes mellitus (35.4%), hypertension (51.6%), cardiovascular disease (45.1%), and current smoker status (38.7%).[35] The incidence of symptomatic tracheal stenosis following percutaneous tracheostomy is comparable to the incidence that occurs after open techniques.[36]

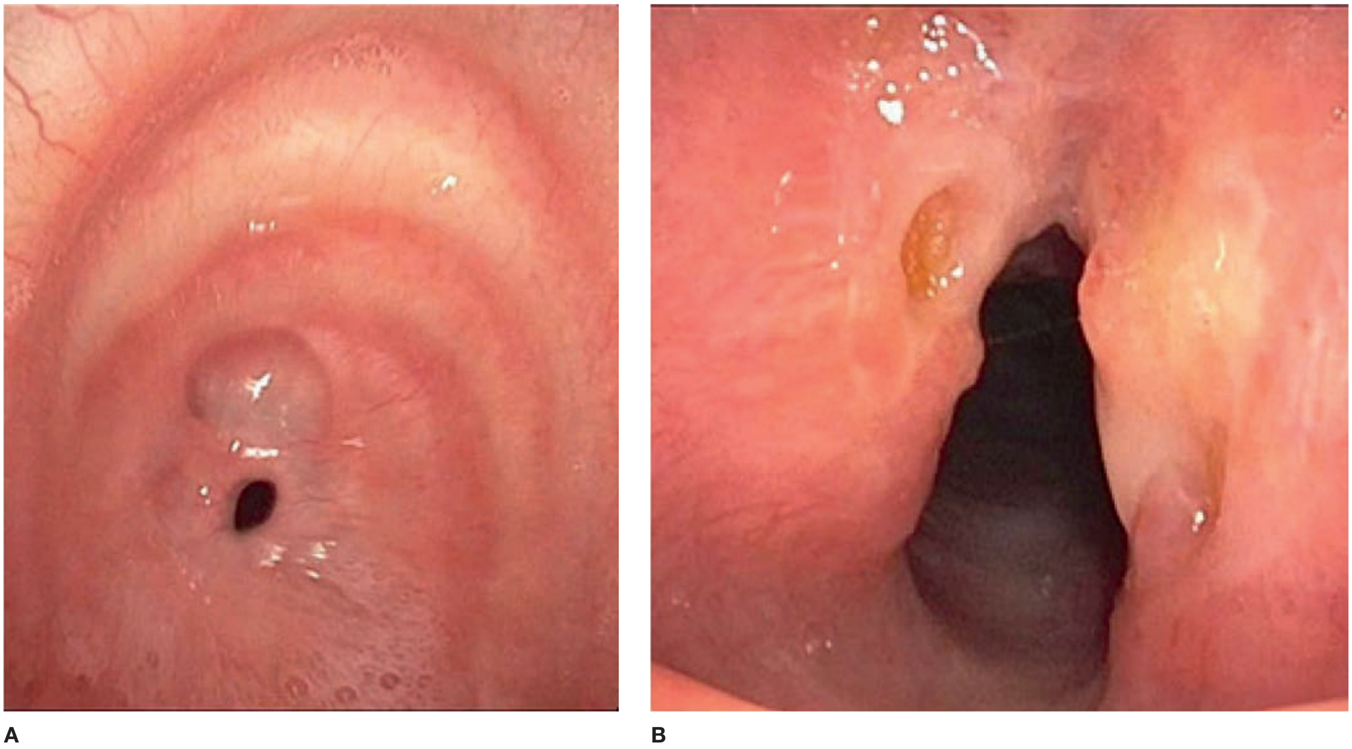
Tracheal stenosis in the region of the tube cuff is related to pressure-induced ischemic injury of the mucosa and cartilage, and its risk can be minimized by use of large-volume, low-pressure cuffs. The duration of translaryngeal intubation also affects the frequency and severity of laryngotracheal stenosis.[37]

Stenosis following tracheostomy may be above the stoma, at the level of the stoma, at the cuff site, or at the tip of the cannula. Damage to the cartilage above the stoma is a common cause of tracheal stenosis after tracheostomy. In addition to ischemic mucosal injury and ischemic chondritis, anterior and lateral tracheal wall damage, with "buckling in" fractures of the cartilage, is an important factor. The fractures can be minimized by avoiding excessive pressure on the cartilage during the procedure, selecting the appropriate size and length of the tracheostomy tube, avoiding infection, and using the lowest possible cuff pressure. Obesity (BMI >30) is a significant independent risk factor for development of posttracheostomy stenosis.[38]

Treatment of PITS/PTTS consists of bronchoscopic dilation, stent placement, and/or surgery for appropriate candidates. Electrocautery needle knife incisions coupled with balloon dilation has been shown to be effective.[39] Silicone stent placement is preferred over metallic stent. Stent placement is most effective when done within 6 months of stenosis and can be successfully removed without restenosis in 40% of patients.[40]

Other Causes of Tracheal Stenosis

Granulomatosis with polyangiitis may present with significant subglottic stenosis, a complication reported in 16% to 23% of patients.[41] Subglottic stenosis may be the only manifestation of granulomatosis



A
B

Figure 47-17 Posttracheostomy stenosis. **A.** Weblike simple stenosis. **B.** A-framed stenosis.

with polyangiitis and may have a clinical course distinct from other manifestations of the disease. Endoscopic biopsy of suspected sites of involvement is positive in only 5% to 15% of cases.

Sarcoidosis may be associated with granulomatous infiltration and obstruction of the upper airways (Fig. 47-19). Laryngeal involvement is more common, but tracheal stenosis has been described. Radiographs may show diffuse tracheal stenosis, which progresses despite corticosteroid therapy. Bronchoscopy may reveal extensive tracheal narrowing.

Pulmonary amyloidosis includes tracheobronchial manifestations. The chest roentgenogram may show diffuse narrowing and wall thickening involving a long tracheal segment. Involvement is diffuse and circumferential, often with ossification of the amyloid deposits (Fig. 47-20). Bronchoscopy demonstrates multiple plaques on tracheal walls or localized tumor-like masses.

Relapsing polychondritis is a rare systemic disease characterized by recurrent episodes of inflammation of cartilaginous structures. Respiratory manifestations are often severe and may be life-threatening. Inflammation occurs in all cartilage types, including the elastic cartilage of the ears and nose, hyaline cartilage of all peripheral joints, and axial fibrocartilage. The most common presenting symptom is pain in the external ear due to auricular chondritis. Respiratory tract involvement may develop years after the first occurrence of auricular chondritis. Symptoms include hoarseness,

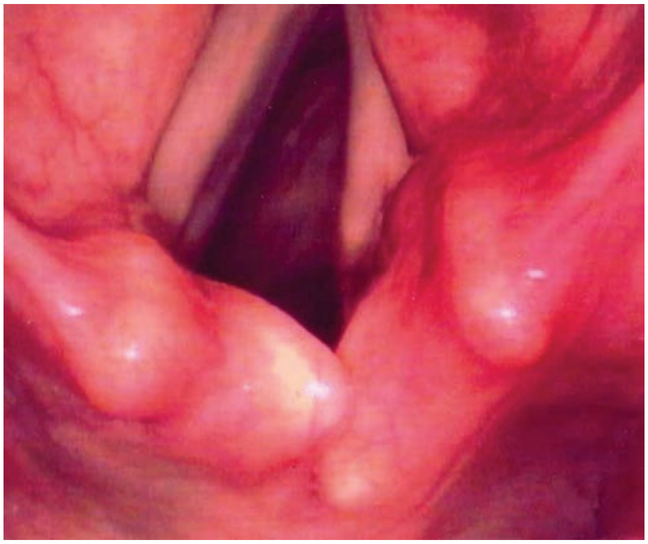


Figure 47-18 Postintubation trauma.

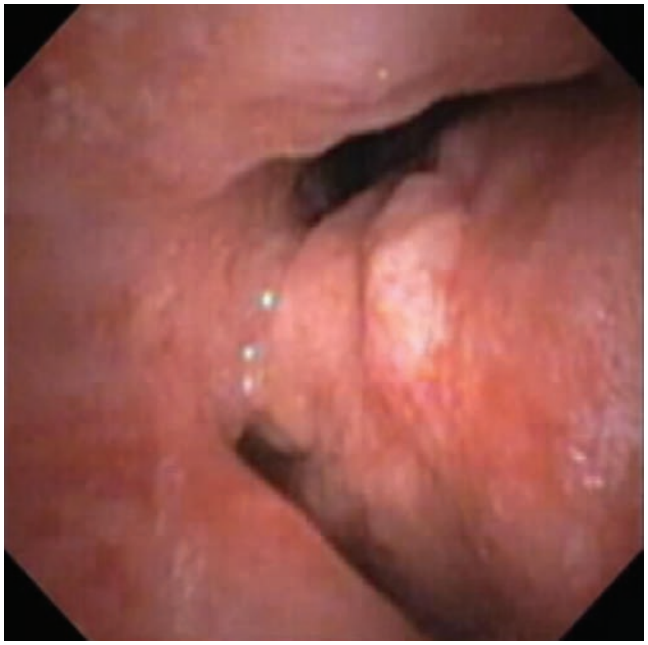

Figure 47-19 Airway sarcoid.

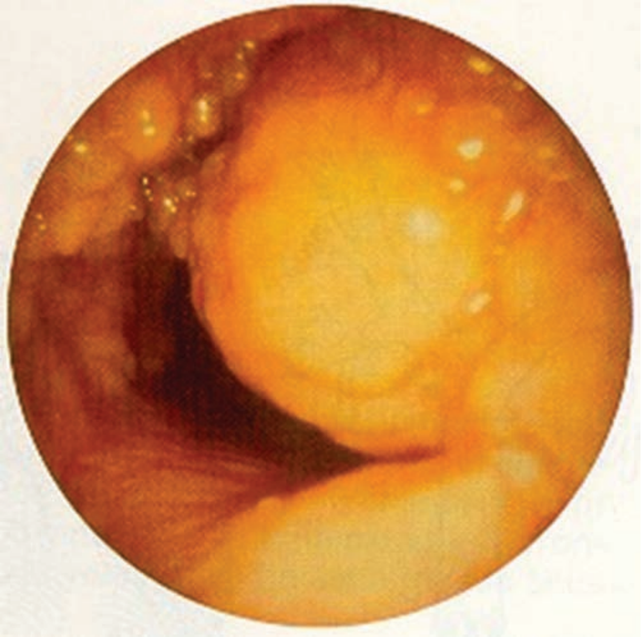

Figure 47-20 Amyloid pseudotumor.

aphonia, and choking. Tenderness over the thyroid and laryngeal cartilages may be present. When the trachea is involved, endoscopic examination shows inflammation and stenosis. CT demonstrates major airway collapse caused by destruction of cartilaginous rings or airway narrowing due to inflammatory edema and fibrosis. CT findings also include diffuse, smooth thickening of the trachea and proximal bronchi; thickened, densely calcified cartilaginous rings; tracheal wall nodularity; and diffuse narrowing of the tracheobronchial lumen. The posterior tracheal membrane is spared.[42]

Tracheopathia osteoplastica is a rare, benign disease of the trachea and major bronchi in which cartilaginous or osseous nodules project into the airway lumen, often causing considerable airway deformity. The posterior membranous portion of the tracheal wall is spared. The disorder may begin just below the larynx, but most often it affects the lower two-thirds of the trachea. Extension into the proximal portions of the major bronchi may be noted. The condition usually occurs over the age of 50 years and may cause severe airflow obstruction. Its etiology is unknown.

On rare occasions, inflammatory bowel disease produces tracheobronchial stenosis and severe airflow obstruction. The associated airway mucosal inflammation may be steroid responsive early in the course of illness. If fibrosis ensues, medical management has limited success.

Idiopathic laryngotracheal stenosis is a diagnosis of exclusion in the absence of a clear, underlying etiology. It predominantly affects women in the fifth decade of life.[43] GERD is commonly concurrently diagnosed. Since most affected patients are females, a hormonal etiology has been proposed. An imbalance in estrogen and progesterone receptor expression has been demonstrated in surgical specimens of resected stenosis.[44] Treatment includes bronchoscopic dilation. Steroid injection and aggressive medical management with proton pump inhibitors and inhaled corticosteroids may prolong the interval between required procedures.[45,46]

In addition to medical management, repeated rigid and flexible bronchoscopy-based interventions aimed at reestablishing airway patency may be necessary, particularly in those who are not considered to be surgical candidates or in those with simple weblike stenosis. In cases of weblike stenosis, radial incisions sparing the posterior membrane are made and then the airway is dilated, using either a balloon or the rigid bronchoscope barrel. With respect to more complex stenosis, endoscopic intervention is generally considered a bridge in patients considered good operative candidates with potentially resectable disease. Unfortunately resection and re-anastomosis is limited by the length of trachea to be resected.[47,48] A multidisciplinary approach incorporating medical and surgical specialists as described by Brichet is utilized in many centers.[49]

■ Tracheomalacia

Tracheomalacia refers to loss of tracheal rigidity and resulting susceptibility to collapse. Tracheomalacia may be diffuse or localized to a tracheal segment. The affected portion may be intrathoracic, in which airway obstruction is accentuated during expiration. Less common is extrathoracic obstruction resulting from cervical malacia, in which airway obstruction is most marked during inspiration. Tracheobronchomalacia is the term used to describe the condition when the mainstem bronchi are involved.

Tracheomalacia in adults may be classified as congenital or acquired. The congenital form, described more extensively in children, is related to a variety of congenital disorders and associated syndromes. The disorder may persist into adult life and is referred to as "idiopathic giant trachea," "tracheomegaly," or the "Mounier-Kuhn syndrome" (Fig. 47-21). Bronchiectasis and recurrent respiratory infections are common. Tracheal diverticuli have been reported in more advanced disease. Although atrophy of the longitudinal elastic fibers and muscularis layer has been described, the etiology of these changes is unclear. The diagnosis is made when the diameters of the trachea or right or left mainstem bronchi exceed the upper limits of normal by 3 or more standard deviations. Patients with Mounier-Kuhn syndrome may benefit symptomatically from airway stenting and tracheobronchoplasty.[50]

Acquired or secondary tracheomalacia in adults may be related to a variety of conditions.[51] Tracheostomy and endotracheal intubation are probably the most common etiologies. Usually, limited, focal weakness of the trachea and excessive dynamic airway collapse are present. Tracheomalacia may be caused by conditions that are associated with chronic pressure on the tracheal wall, inflammation of the cartilaginous support or mucosa, interference with tracheal

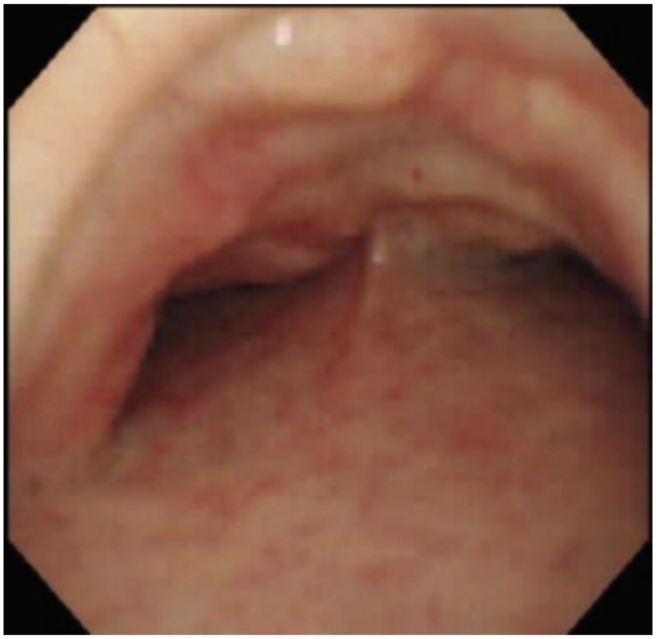

Figure 47-21 Bronchoscopic view of tracheomegaly or Mounier-Kuhn syndrome.

blood flow, or chronic infection. Traumatic injury to the central airways or surgical interventions also may lead to tracheomalacia.

Symptoms of tracheomalacia include dyspnea, a seal-barking paroxysmal cough, recurrent pulmonary infections, and respiratory failure in a small subset.[52] Many of these patients will also have decreased exercise tolerance and, in severe cases, impaired quality of life.

Tracheomalacia is defined as a reduction in cross-sectional area of greater than 50% during expiration on CT imaging. However, this cut point may not be discriminatory enough to detect clinically significant tracheomalacia.[53] Bronchoscopic visualization can confirm significant narrowing of the tracheal lumen during regular, forced expiration.

Application of continuous positive airway pressure (CPAP) has been reported to be as beneficial as pneumatic splint for the airways. Tracheobronchoplasty may be useful in selected patients and has been shown to improve quality of life and exercise tolerance.[52] Airway stents can be used to identify patients that may benefit from surgical airway stabilization.[54,55] In select patients who are not surgical candidates, but who derive both symptomatic and objective benefit from airway stents, silicone stents may be used for long-term management with appropriate monitoring for complications. Optimal medical management includes treatment of associated infections and of distal airway disease.

■ Extrinsic Compression of the Central Airway

The upper airway is subject to extrinsic compression by a variety of pathologies that involve adjacent structures. The compression may affect the intrathoracic trachea or extrathoracic trachea and upper airway.

Mediastinal Masses and Lymphadenopathy

Rarely, mediastinal masses present with serious limitation to airflow that develop either acutely or indolently. Common symptoms include chest pain, fever, dyspnea, and cough. The anterosuperior compartment is the most common site of mediastinal malignancies. Thymic neoplasms and lymphoma are the most common malignancies, followed by neurogenic tumors and teratomas. Both Hodgkin and non-Hodgkin lymphomas may be manifested by severe respiratory compromise due to airway compression. A similar syndrome may be due to a metastatic tumor in the mediastinal lymph nodes arising from bronchogenic or other carcinomas.

Patients with large mediastinal masses present a challenge during the perioperative period because of the potential for development of acute UAO and other respiratory complications. In adults, complete airway obstruction during induction of anesthesia is rare. Serious pulmonary complications develop intra- and postoperatively in about 4% and 7% of patients, respectively. Complications may occur while the patient is placed in the supine position, during induction, or following extubation. Patients with severe symptoms, including stridor, and those with greater than 50% airway obstruction, appear to be at high risk for respiratory complications; asymptomatic patients are at significantly less risk. Patients with reduced peak expiratory flow and mixed obstructive–restrictive patterns on pulmonary function testing also appear to be at increased risk for postoperative complications.

Middle mediastinal masses include benign cysts that are bronchogenic, enterogenous (duplication), pericardial, pleural, and thymic in origin. Most bronchogenic cysts are asymptomatic. However, some evoke cough, chest pain, and dyspnea. Severe respiratory distress and compressive symptoms can occur. Usually, cyst contents appear to have the density of water on CT or MRI. Mucoid contents may give the impression of solid appearance on CT. Surgical resection and transthoracic or transbronchial drainage are options for management. Surgical intervention appears to be the preferred treatment in patients who are symptomatic. The role of interventions, including surgery, in asymptomatic patients is controversial. Enterogenous cysts are usually removed surgically.

Enlarged mediastinal lymph nodes that compress the airway may arise from infectious and noninfectious benign etiologies. One notable example is fibrosing mediastinitis, defined as the presence of excessive mediastinal fibrous tissue that tends to invade and destroy normal structures. The entity is thought to represent a reaction to an infectious granulomatous disease, especially histoplasmosis. The incidence in populations exposed to histoplasmosis remains low. Constriction of the central airways and vessels and the resulting cardiopulmonary limitations may develop several years after the initial infection. Hemoptysis is common, as are cough, dyspnea, and chest pain. CT imaging shows mediastinal fibrosis, calcification, and compression of mediastinal structures. Bronchoscopic findings include concentric airway narrowing and mucosal edema with hyperemia. Unfortunately, hemoptysis tends to be recurrent, and the disease does not respond to corticosteroids or antifungal agents. Surgical intervention is generally ineffective and may be hazardous.

Neck- and Thyroid-Related Causes

Retrosternal extension of a diffuse goiter may cause extrathoracic or intrathoracic airway obstruction. Patients with substernal goiter may have obstructive respiratory and gastrointestinal symptoms.[56] Orthopnea is prevalent when the goiter is intrathoracic and may be enhanced by obesity. Flow–volume loops show evidence of UAO in one-third of patients. Lack of correlation has been reported between symptomatic obstruction and CT findings.[57]

Laryngoceles and saccular cysts, which are abnormal dilatations of the laryngeal saccule (ventricle), are uncommon. Saccular cysts usually are filled with mucus. Laryngoceles communicate with the laryngeal lumen, resulting in air-filled structures noted on radiographic studies. Laryngoceles may be internal (i.e., confined to the larynx), external (i.e., extending into the thyrohyoid membrane superiorly), or combined. Most are asymptomatic. Hoarseness, dysphagia, pain, or signs of airway obstruction or infection may occur. A neck mass during the Valsalva maneuver may be detectable. Pyocele formation (i.e., infection in the laryngocele) may result in airway obstruction, aspiration pneumonia, or infection of the lateral pharyngeal space. The incidence of laryngeal carcinoma in association with laryngoceles makes close evaluation necessary. Endoscopic and surgical approaches may be employed in management.

Parathyroid cysts may be located in the neck or mediastinum. Fifty percent are accompanied by clinical hyperparathyroidism. Paroxysmal symptoms of airway obstruction can develop. Surgical excision is the treatment of choice; results are generally good.

Cervical osteophytes, common in the elderly, are related to either degenerative spinal arthritis or more generalized idiopathic skeletal hyperostosis; the osteophytes may be associated with dysphagia. In addition, airway narrowing and ulcerations due to osteophytes have been reported. The airway compression may make even elective endotracheal intubation difficult, despite adequate preoperative evaluation.

Finally, significant upper airway compression may arise from cervical lymph node involvement with infectious or malignant disorders, hematomas or pseudoaneurysms (related to trauma, surgical interventions, central line placement, or coagulation abnormalities), abscess formation, or other expanding lesions in the soft tissue of the neck.

Diseases of the Esophagus

Involvement of the trachea, glottis, or vocal cords by advanced esophageal cancer is common and associated with a poor prognosis; estimated 1-year survival is less than 10%. Airway obstruction

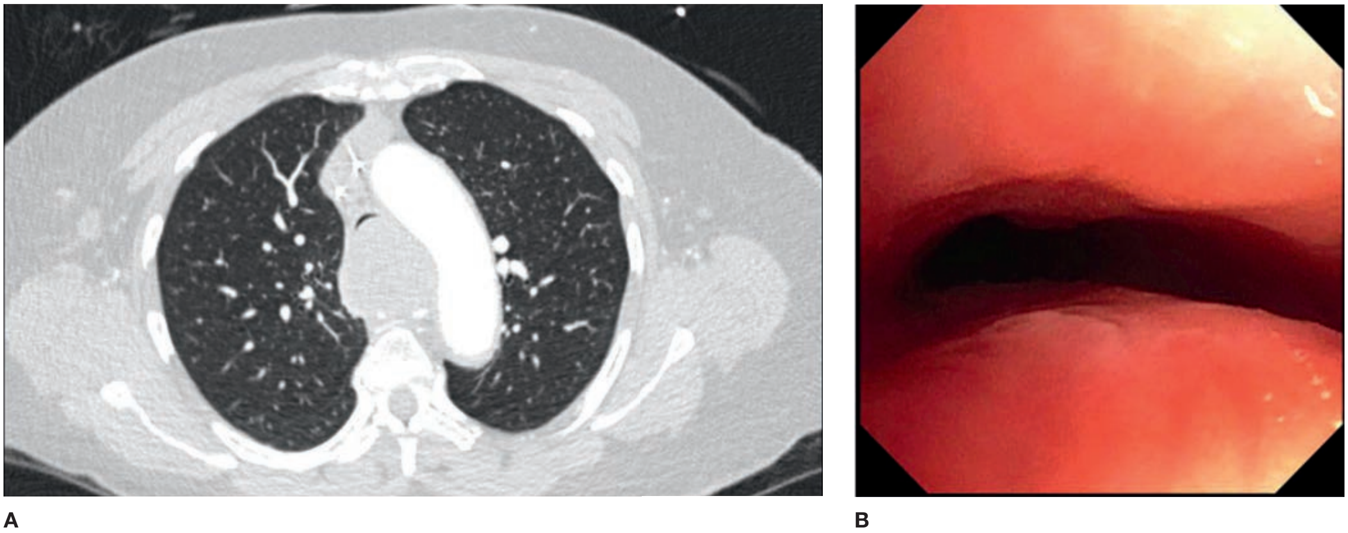

Figure 47-22 Distal tracheal compression due to esophageal tumor. **A.** CT view. **B.** Bronchoscopic view.

requiring stent placement is associated with a median survival of 1 to 4 months after the placement (Fig. 47-22A, B).[58] Tracheal obstruction may develop if an esophageal stent is placed in the setting of significant tracheal compromise. Development of tracheoesophageal fistula represents a devastating complication.

Placement of stents simultaneously in the trachea and esophagus is effective palliation for a tracheoesophageal fistula.[59] If such double stenting is anticipated for a fistula or for simultaneous esophageal and tracheal obstructions, the tracheal stent is placed first to ensure patency of the airway, followed by the esophageal stent. Palliative external or local radiation therapy, chemotherapy, or other treatment modalities (e.g., PDT) may be effective with or without accompanying airway interventions. The risk of esophageal disruption and rupture should be considered if stenting is performed after these local measures are employed.

Achalasia may cause a variety of pulmonary complications, including cough, aspiration with pneumonia or abscess formation, and rarely UAO. Tracheal compression by a dilated megaesophagus is the usual etiology. Ensuring patency of the airway and decompressing the esophagus are necessary in urgent management.

Vascular Abnormalities

Vascular rings, defined as anomalies of the aortic arch or its branches that compress the trachea or esophagus, are rare in adults (incidence <0.2%). Respiratory symptoms are common. Right-sided aortic arch occurs in less than 0.1% in adults and may be associated with complete vascular rings, while double aortic arch and right-sided aortic arch with aberrant left subclavian artery appear to be the most common etiologies of vascular rings in adults.

The right-sided aortic arch usually crosses over the right main-stem bronchus and descends on either the right or the left side. The vascular ring is usually completed by the ligamentum arteriosum arising from the descending aorta, an aberrant left subclavian artery, or an aortic diverticulum. With a double aortic arch, the left arch crosses over the left main-stem bronchus and joins the descending aorta to complete the ring; the ligamentum arteriosum does not contribute to the vascular ring. Symptoms, resulting from malacia of the compressed airway and resultant dynamic airway obstruction, may be misdiagnosed as exercise-induced asthma. An increase in aortic diameter due to rising blood pressure during exercise, intravenous fluid administration, or anatomic changes with aging may contribute to symptoms. Surgical intervention is indicated in symptomatic patients.

Pulmonary artery sling with anomalous origin of the left pulmonary artery from the right pulmonary artery is very rare in adults. In neonates, the condition is symptomatic and can be fatal without surgical intervention. However, in adults the condition is usually diagnosed incidentally on imaging a patient who has no significant symptoms. This disorder may be associated with a complete tracheal ring, forming the "sling-ring" complex. This condition may present with a right paratracheal mass noted on the chest radiograph.

Compression of the trachea by large aortic or innominate artery aneurysms or pseudoaneurysms may occur and complicate management in the perioperative period. Surgical repair is indicated to relieve symptoms.

■ Foreign Body Aspiration

Foreign body aspiration, more common in children than adults (in whom the peak incidence is in the sixth decade), is usually recognized from the patient's history. Foreign bodies commonly lodge in the bronchi after migrating through the trachea. In adults, food products are the most commonly aspirated material. The penetration syndrome, defined as the sudden onset of choking and intractable cough after aspirating a foreign body, with or without vomiting, is often followed by persistent cough, fever, chest pain, dyspnea, and wheezing. Impairment of the normal protective airway mechanisms is common; among the frequent associations are neurologic disorders, trauma with loss of consciousness, sedative or alcohol use, poor dentition, and advanced age. Emergency measures, entailing a food extractor or the Heimlich maneuver, can be life-saving. Flexible bronchoscopy is usually successful in removing foreign bodies, although backup rigid bronchoscopy should be available and is preferred as the primary procedure at some centers. A complicating chemical bronchitis from aspiration of vegetables or nuts may affect visualization and management of the foreign body. Certain nut oils also cause a significant foreign body mucosal reaction, resulting in the development of granulation tissue that may be misdiagnosed as endobronchial tumor.

■ Trauma

A variety of traumatic injuries may eventuate in UAO.

Facial Trauma

Emergency access to the airway is necessary in up to 6% of cases of facial trauma complicating motor vehicle accidents and other causes of crush injuries. If intubation is difficult or impossible due to the injury or related airway obstruction, emergency cricothyroidotomy or tracheostomy must be considered.

Laryngotracheal Injuries

Blunt and penetrating injuries to the laryngotracheal airway are rare. Without a high index of suspicion, clinicians may miss the diagnosis. The incidence of penetrating injuries appears to be increasing.

Stridor, wheezing, dysphonia, hemoptysis, and general neurologic deficits are common. Cervical crepitus and subcutaneous emphysema also may be present. Cervical ecchymoses and hematomas, pneumomediastinum, and pneumothorax should prompt consideration of a laryngotracheal injury.

Management includes prompt securing of the airway, but blind endotracheal intubation should be avoided, since it carries the risk of complete airway obstruction. Some experts recommend tracheostomy as the primary airway management strategy. Awake fiberoptic intubation can be useful. Flexible fiberoptic laryngoscopy, rigid or flexible bronchoscopy, and CT imaging may be helpful in assessing the degree of injury. Unfortunately, the mortality of laryngotracheal injuries remains high.[60] Thoracic injuries and closed head injuries are commonly associated pathologies that can influence management and prognosis.

Inhalation Injuries

Thermal and chemical injuries to the upper respiratory tract may lead to serious consequences, including airway obstruction. The mortality rate increases significantly when burns are accompanied by inhalational injury.[61] Symptoms can be delayed in becoming manifest, making early recognition and intervention vital in the management of patients with inhalational injuries. The presence of cough, dyspnea, hoarseness, or loss of consciousness, or the findings of singed nasal hairs, carbonaceous sputum, or burns involving the face indicate a high likelihood of inhalation injury.

Early flexible bronchoscopy remains important in evaluation and management of patients with inhalation injuries, enabling the assessment of the extent and severity of the injury, procurement of samples for bacteriologic studies, and bronchoscopic intubation, as necessary.[62] Translaryngeal intubation is the standard method of securing the airway in inhalation injury; early tracheostomy is used in some centers. A role for prophylactic corticosteroids or antibiotics is currently not supported by published reports. Significant tracheal stenosis may develop in patients who survive the initial insult especially in those with larger total body surface area involved, higher grade of inhalational injury, and longer duration of intubation.[63]

■ Endotracheal Tube–Related Trauma

Postextubation stridor due to glottic edema, laryngospasm, or laryngotracheal stenosis is a serious event. Risk factors include duration of intubation, emergency intubation, and height/endotracheal tube size ratio.[37] Reintubation rates for UAO due to endotracheal tube–related trauma in critically ill patients have been reported to range from 4% to 33%. An "acceptable" rate is considered to be 5% to 15%. Clinical practice guidelines support the use of pre-extubation glucocorticoids in patients deemed high risk for post extubation stridor who have failed a cuff leak test.[64]

Translaryngeal intubation may also produce either unilateral or bilateral vocal cord paralysis. Affected patients may present with hoarseness or airway obstruction. Findings may occur immediately after extubation or be delayed. Prolonged intubation, use of a large endotracheal tube, placement of the tube cuff close to the vocal cords, or use of excessive cuff pressure are risk factors. The condition usually resolves spontaneously within 10 weeks.

Vocal cord (contact) granuloma may develop 4 to 6 weeks after intubation. Symptoms include prolonged hoarseness, exertional dyspnea, and stridor. Management, using antireflux medications, inhaled and systemic corticosteroids, antibiotics, botulinum toxin injection, speech therapy, smoking cessation, and rest of the voice are usually successful. Surgical intervention is reserved for cases that fail conservative management.

On occasion, dislocation of the arytenoid cartilages occurs during intubation. Rheumatoid arthritis that affects the cricoarytenoid cartilage is a risk factor for this condition. Rigid bronchoscopy or surgical interventions may be needed to reduce the dislocation. Other disorders that may cause complications during intubation include hyperostosis of the cervical spine due to ankylosing spondylitis and cricoarytenoid joint disease due to systemic lupus erythematosus.

■ Neuromuscular Disorders

Neuromuscular disorders may affect the bulbar muscles, many of which surround the upper airway (Fig. 47-23). When this occurs, resistance to airflow is increased, and the flow–volume loop often shows an inspiratory flow plateau typical of variable extrathoracic UAO. In addition, a pattern of flow oscillations during inspiration ("sawtooth pattern") may be seen.[65] The abnormal flow pattern, first noted in patients with sleep apnea,[66] is commonly seen in extrapyramidal disorders, myasthenia gravis, and motor neuron disease; it may also be seen in patients who have functional stridor and wheezing (see "Vocal Cord Dysfunction," below). In extrapyramidal disorders, the flow oscillations correspond to vocal cord tremor. In motor neuron diseases, muscle denervation causes irregular muscle fasciculation, resulting in tremor of upper airway muscles.

Upper airway symptoms may be seen in Shy–Drager syndrome with extrapyramidal involvement and in Parkinson disease.[67,68] Patients may present with symptoms of chronic dyspnea or with stridor and respiratory failure relieved by endotracheal intubation or tracheostomy. Bilateral vocal cord paralysis may also occur with familial bulbar spinal muscle atrophy, postpoliomyelitis syndrome, Parkinson disease, multiple sclerosis, acute poliomyelitis, amyotrophic lateral sclerosis, Guillain–Barré syndrome, brain stem stroke, and large cerebral hemisphere stroke. Dystonic extrapyramidal reactions due to neuroleptic medications (e.g., haloperidol) may

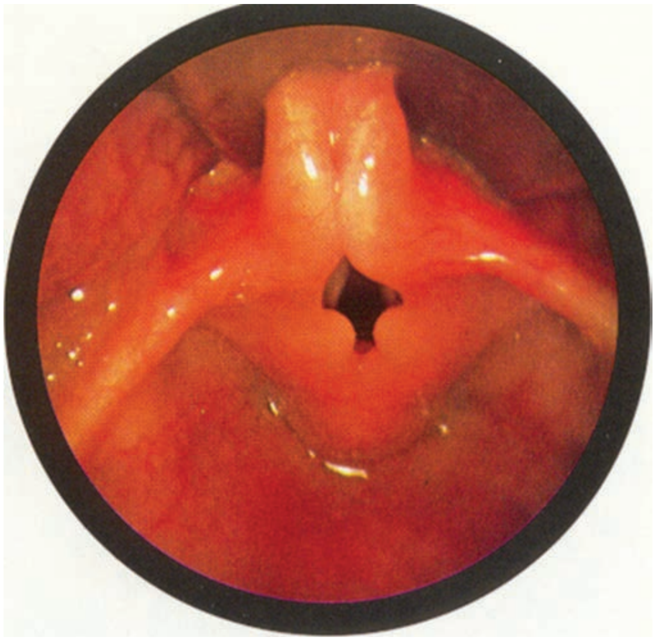

Figure 47-23 Laryngomalacia.

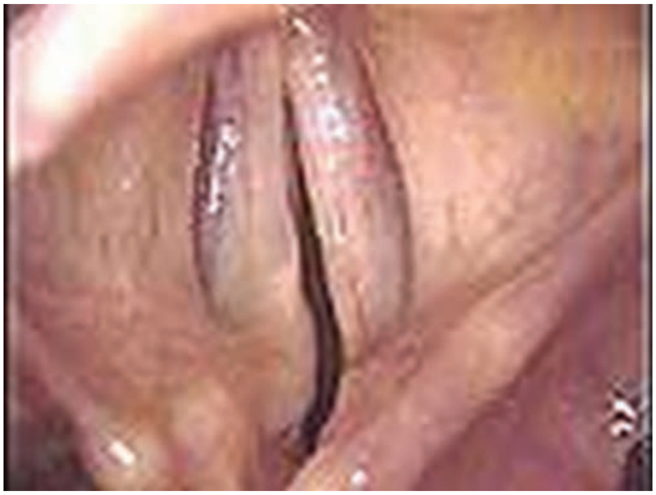

Figure 47-24 Bilateral vocal cord paralysis.

cause significant UAO. The usual reactions to these medications are akathisia, dyskinesia, dysarthria, and dystonic reactions such as torticollis. Laryngeal–pharyngeal dystonia may cause severe upper airway dysfunction, and if not reversed, symptoms can last for days or lead to respiratory arrest.

■ Bilateral Vocal Cord Paralysis

Bilateral vocal cord paralysis is a serious condition resulting in nocturnal stridor, oxygen desaturation, sleep disruption, or, in extreme cases, acute respiratory failure (Fig. 47-24). Thyroidectomy is the most common cause of bilateral recurrent laryngeal nerve injury, with its consequent bilateral vocal cord paralysis.[69] As mentioned earlier, bilateral vocal cord paralysis may occur with numerous neurologic conditions. Nonneurologic causes include endotracheal intubation injury, laryngeal trauma, infection, and thoracic aortic aneurysm. Bilateral vocal cord paralysis results in abnormalities of inspiratory flow and a distinctive flow–volume loop.

Spontaneous recovery of vocal cord motility is rare after surgical injury of the recurrent laryngeal nerve. For those patients showing no spontaneous functional recovery, several surgical techniques to achieve a glottic space enlargement are available. CO_2 laser endoscopic surgery has led to shorter hospitalization and higher patient compliance.[70,71] Endoscopic surgeries include arytenoidectomy with or without posterior true and false cord cordectomy.[72] Surgeries aim to improve breathing with minimal deglutition impairment and improve quality of voice. Restenosis of the glottis space is the main problem that leads patients to reoperations.

■ Vocal Cord Dysfunction

The glottis plays an active role in adjusting airflow, both voluntarily and through reflex control from laryngeal and lung receptors. During a normal respiratory cycle, the vocal folds widely abduct during inspiration and slightly adduct during expiration. Occasionally, the glottis can become dysfunctional in the absence of organic disease. The disorder, most commonly called vocal cord dysfunction or paradoxical vocal fold motion, is characterized by paradoxical closure of the vocal cords intermittently during inspiration. The glottis angle formed by the true vocal folds can become acute and cause airflow obstruction during inspiration and/or expiration. The mechanism is unknown but likely multifactorial. Laryngeal hypersensitivity has been associated with reflux, upper respiratory tract infections, postnasal drip, irritants, and exercise, as well as psychogenic factors.[73]

Signs and symptoms of vocal cord dysfunction resemble those of laryngeal edema, laryngospasm, vocal cord paralysis, or asthma.[74] Wheezing or stridor and shortness of breath are typical and are often so dramatic that they suggest acute asphyxia and respiratory failure. Intubation and other emergency measures are used frequently. However, symptoms are often brief and may remit without intervention. Distinguishing physical examination findings include tracheal localization of wheezing or stridor with absent peripheral airway expiratory wheezing; however, it should be understood that this might also occur during severe asthma attacks.

On pulmonary function testing, patients with vocal cord dysfunction typically have normal spirometry without evidence of obstructive ventilatory defect.[75] Some may demonstrate a pattern of variable extrathoracic airway obstruction, resulting in an increase in the ratio of $FEF_{50\%}$ to $FIF_{50\%}$. Some patients show a pattern of "sawtoothing," or fluttering of the inspiratory limb of the flow–volume loop, representing fluctuations in the abnormal cord motion (Fig. 47-25). Often, attempts to perform the flow–volume loop maneuver generate variable results from test to test. A normal alveolar–arterial oxygen gradient and absence of bronchial hyperresponsiveness are other clues to the diagnosis.

The diagnosis of vocal cord dysfunction is confirmed during direct visualization of the vocal cords during an attack. The anterior two-thirds of the vocal folds adduct and give the presence of a posterior diamond-shaped chink in the folds during inspiration.[76]

The true prevalence of the disorder is unknown because it is often mistakenly diagnosed as asthma, and many patients in fact have both vocal cord dysfunction and asthma.[77] Patients without asthma are predominantly women who have been misdiagnosed as having asthma for an average of 5 years. Typically, patients have been treated with large doses of oral corticosteroids and have experienced frequent emergency room visits, hospitalizations, and endotracheal intubations.

Psychiatric disorders are common in these patients.[78,79] Major psychiatric disorders, personality disorders, and sexual and physical

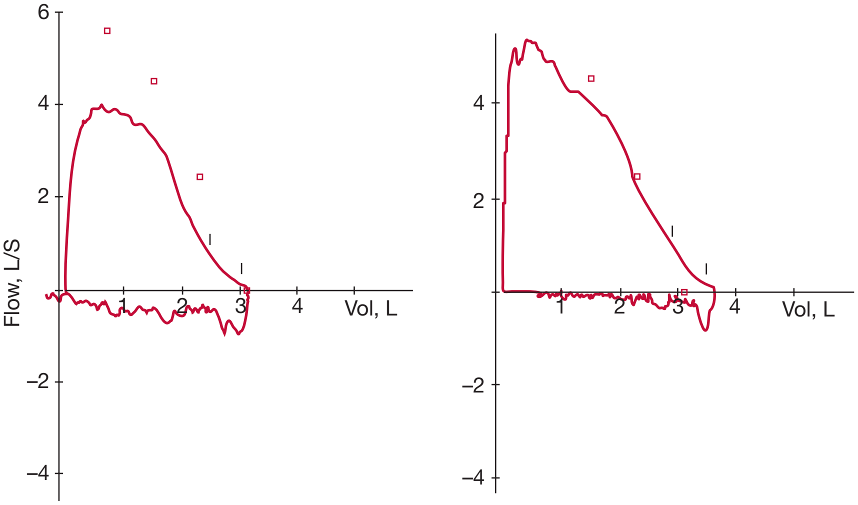

Figure 47-25 Variable extrathoracic obstruction due to vocal cord dysfunction. Two consecutive flow–volume loops from a young woman with inspiratory stridor. Variable effort accounts for the differences in configuration. $FEF_{50\%}/FIF_{50\%}$ in each is very high. The inspiratory loop is flat and demonstrates a sawtooth pattern. This pattern has also been associated with sleep apnea syndrome and various neuromuscular disorders.

abuse are commonly uncovered. Whereas many patients are unaware of their self-induced wheeze or stridor, others appear to derive secondary gain from their symptoms and manifest factitious illness. A high index of suspicion is warranted when the adventitious sounds are loudest over the neck in a patient who presents with wheezing, stridor, or both. Despite their respiratory distress, patients often have little difficulty completing full sentences and can hold their breath; the laryngeal-induced sounds disappear during a panting maneuver.

Treatment includes discussion of the diagnosis with the patient, discontinuation of unnecessary medications, and referral to a speech therapist or psychotherapist. The response to bronchodilator therapy is usually poor. Use of continuous positive airway pressure or administration of an inhaled helium–oxygen mixture may alleviate symptoms during an acute attack.[80] Botulinum toxin injection may be used in refractory cases.[81]

Angioedema

Angioedema is characterized by well-demarcated swelling of the face, lips, tongue, and mucus membranes of the nose, mouth, and throat. When the larynx is involved, UAO may occur and can be fatal. In most instances, the cause of angioedema is unclear; prior exposure to common allergens, such as drugs, chemical additives, and insect bites, should be suspected.

Counterintuitively, the most common causes of angioedema are not IgE initiated. They include reactions to histamine-releasing drugs, such as narcotics and radiocontrast materials, aspirin, other nonsteroidal anti-inflammatory drugs, and angiotensin-converting enzyme inhibitors. Hereditary angioedema, a rare cause of UAO, is an autosomal-dominant trait that causes a deficiency in production or function of C1 esterase inhibitor, a serum protease inhibitor that regulates the complement, fibrinolytic, and kinin pathways. Hereditary angioedema (HAE) is characterized by painless nonpitting edema of the face and upper airway. The disorder usually begins in childhood and becomes more prominent in adolescence. Swelling progresses over many hours and then resolves spontaneously over 1 to 3 days. Despite the slow progression, death may occur from laryngeal obstruction. Physical stimuli (cold, heat, stress) and circulating immune complex diseases (e.g., due to serum sickness or systemic lupus erythematosus) are also known to cause angioedema.

Emergency management includes foremost securing the airway. Epinephrine is used for angioedema with anaphylaxis. Administration of corticosteroids and antihistamines are often used, although current evidence suggests that such a therapy is rather ineffective in kinin-induced angioedema.[82] Thus, symptom-related medical care should be provided until the swelling has disappeared. Treatment of HAE includes C1-inhibitor concentrate, recombinant C1 inhibitor, kallikrein inhibitors (ecallantide) and bradykinin type 2 receptor antagonists (icatibant).[83–86]

MANAGEMENT OF UPPER AIRWAY OBSTRUCTION

Key elements in the management of UAO include general principles, securing the airway, and specific interventions.

General Management

The primary goals in management of any patient with UAO are assurance of adequate oxygenation and ventilation and management of the underlying condition. If airway obstruction is partial, and the patient's condition is stable, close monitoring and diagnostic studies are appropriate. Depending upon the underlying etiology, temporary measures may include close observation in an intensive care unit, elevation of the head of the bed, administration of humidified oxygen, use of a helium–oxygen inhalation mixture (heliox), systemic corticosteroids, and inhaled racemic epinephrine, pending definitive medical or surgical management.

Heliox may be useful in management of UAO when the obstruction is temporary and reversible. The physiologic rationale for heliox is based upon a reduction in work of breathing achieved through administration of a low-density gas. In particular, heliox has a lower density than does oxygen, room air, or a mixture of the two, resulting in conversion of the predominantly turbulent flow at the site of obstruction to a more laminar pattern. Furthermore, since laminar flow requires a smaller pressure gradient than turbulent flow to achieve the same flow rate, the accompanying work of breathing is less (see Chapter 10). The major limitation of the modality is an inability to deliver gas with an inspiratory fraction of oxygen ($F\text{I}_{O_2}$) of more than 40%. Despite physiologic evidence and clinical reports of efficacy, prospective, randomized studies demonstrating improved outcome in patients receiving heliox are lacking, as are data supporting use of corticosteroids or inhaled epinephrine in airway obstruction from a variety of causes.

Securing the Airway

Although under controlled circumstances, a significant portion of the so-called difficult airways and intubations may be identified in the course of a thorough preoperative assessment, the patient with impending airway obstruction presents a challenge. Under such circumstances, a critical first concern is deciding whether an artificial airway is needed emergently.[87] Regardless of the airway utilized, emphasis is placed on ensuring adequate oxygenation and ventilation.

Airways judged unsafe for routine management may be addressed according to the "difficult airway algorithm" recommended by the American Society of Anesthesiologists (see Chapter 146).[88] A difficult airway is defined as a clinical circumstance in which a conventionally trained anesthesiologist experiences difficulty using face mask ventilation, endotracheal intubation, or both.

Airway access in emergency situations may be challenging because the patient frequently is critically ill and can deteriorate quickly. The likelihood of a difficult intubation can be estimated by using the Mallampati score or a modification of the score to assess potential laryngeal exposure and prospects for adequate airway visualization.

A number of parameters, such as mouth opening distance, jaw size, thyromental distance, and cervical range of motion, have been incorporated into airway assessment scoring systems; each parameter has limited sensitivity and specificity. Combining scoring systems provides better accuracy of prediction. The "rule of threes," which is a useful, simple bedside tool, predicts successful direct laryngoscopy if the examiner can place three finger breadths (~6 to 7 cm) between the upper and lower teeth, the mandible and hyoid bones, and the thyroid cartilage and sternal notch. In the emergency setting of UAO, the most experienced physician available should secure the airway. Appropriate equipment and monitoring, along with backup resources for alternative and invasive airway management, should be available.

A variety of invasive and noninvasive techniques are available as alternatives to standard, laryngoscopy-guided orotracheal intubation. Invasive methods include surgical and/or percutaneous tracheostomy, surgical and percutaneous transtracheal (needle) cricothyrotomy, translaryngeal-guided or "retrograde" intubation, fiberoptic endotracheal intubation, and use of a rigid ventilating bronchoscope. Noninvasive techniques include use of specialized laryngoscope blades, Glidescope, guiding and lighted stylets, directional tip control tubes, and esophageal–tracheal (Combitube) or laryngeal mask airways. In selected circumstances, tactile intubation, nasotracheal intubation, or blind orotracheal intubation may be employed.

Cricothyroidotomy

Cricothyroidotomy (either surgical or based on Seldinger technique) has a long history of use in emergency access to the airway when more conservative approaches fail or are contraindicated. In early reports, a high incidence of laryngeal stenosis during long-term follow-up was noted, perhaps related to the presence of infectious laryngeal disease, the use of large-bore tubes, and prolonged intubation.[89] More contemporary reviews indicate a much lower (1.1%) incidence of airway stenosis following cricothyroidotomy.[90] The procedure is useful for short-term airway control; tracheostomy should be considered if prolonged airway access is required.

Tracheostomy

Most tracheostomies are performed on intubated patients in the intensive care unit. Percutaneous tracheostomy is rapidly becoming the method of choice in the intensive care unit and is associated with acceptable intraoperative and postoperative complication rates.[91,92] Advantages of the technique over the traditional procedure include low cost, short procedure time, and elimination of the need to transport critically ill patients to the operating room. Adaptation of percutaneous techniques for emergency situations also has been described.

In a review of more than 1100 patients who underwent tracheostomy, 76% were performed in patients who required prolonged ventilation, 6% for UAO, 7% for extensive maxillofacial trauma, and 11% as an adjunct for head and neck or chest surgeries; only 0.26% were performed as emergency procedures. Overall mortality was 0.7%.[93]

■ Interventional Bronchoscopic Techniques

Interventional bronchoscopy is discussed in Chapter 34. Use of these techniques for managing UAO is well established and is briefly summarized in the following paragraphs.

Rigid bronchoscopy allows oxygenation, ventilation, and application of various diagnostic and therapeutic interventions, including debridement of obstructing lesions, control of bleeding, and removal of foreign bodies. Complications include anesthetic risks; barotrauma; damage to teeth, lips, or gums; airway perforation; bleeding; and mucosal injury.

Thermal modalities may be used to devitalize tissue prior to mechanical debridement or to cauterize the base of lesions following debulking. Electrocautery, laser (Nd-YAG, CO_2), and argon plasma coagulation (APC) can be applied through rigid or flexible bronchoscopy. Side effects include bleeding, perforation, airway fire, and damage to cartilage. All thermal modalities are about equally as effective at achieving airway patency, and often the method of choice is clinician preference. APC has the best hemostatic properties.

Photodynamic therapy (PDT) is based on the principle of targeted tissue apoptosis after local activation of a systemically injected photosensitive chemotherapeutic agent. In essence, PDT creates a phototoxic cell reaction when nonthermal laser light is applied by bronchoscopy and activates a drug trapped in these target cells. The major disadvantage of this technique is that the tissue necrosis occurs within 48 to 72 h and as such the ability to debride the airway is delayed for several days. Bleeding and obstruction from necrotic tumor and edema are potential immediate complications. PDT may also result in airway perforation.

Standard cryotherapy, based on repeated freeze–thaw cycles to achieve cell necrosis and tissue damage, is used in benign and malignant disorders of the upper airway. A flexible cryoprobe can be inserted via flexible or rigid bronchoscopy and uses extremely cold gas at the tip cooled to −40°C to −80°C to freeze tissue. Cryotherapy has excellent hemostatic effects; the incidence of perforation or bleeding is low. Due to the delayed beneficial effect, cryotherapy is not usually used under emergent conditions. A method of debulking obstruction uses a cryobiopsy technique in which the tissue is simply frozen to the probe and then sheared from the surface, obviating the thaw cycle. Applied in this fashion, cryotherapy can be used for the immediate treatment of airway obstruction, although when used in this fashion it has less of a hemostatic effect than the thermal modalities. In addition, cryotherapy has the advantage over other thermal modalities in that cartilage is cryoresistant whereas malignant tissue is generally cryosensitive. An endoluminal cryospray catheter has been developed and has been used effectively to treat tracheal stenosis due to both benign and malignant causes.[94]

Finally, external beam radiation and brachytherapy are useful modalities for palliative management of airway obstruction and hemoptysis. For external beam radiation, unwanted exposure of adjacent structures is a limiting factor, while hemorrhage, radiation bronchitis, and fistulae with surrounding structures are known complications of radiotherapy. The maximal effect of all radiation techniques is delayed days to weeks, and there is a risk of worsening of obstruction during therapy due to airway edema.

■ Airway Stents

Airway stents are used in the palliative management of both benign and malignant airway obstruction.[95] Available tracheal stents include expandable metal, silicone, and hybrid prostheses. Major complications include stent migration, granulation tissue formation, and stent interference with mucociliary clearance. In a series of more than 1500 patients who had stents placed for UAO due to benign or malignant disorders, stent migration was reported in 9.5%, granulation tissue formation in 7.9%, and obstruction in 3.6%. Due to concerns regarding stent fracture and the likelihood that stents will remain in place longer in benign disease, the FDA posed a warning on the use of metallic airway stents for this indication. Currently, metallic stents are only recommended in benign disease for patients who are not candidates for or have failed a trial of silicone stent placement. Recent advances in 3D airway modeling and printing have allowed for the development of customized patient-specific silicone stents that have had promising results in patients with complex stenosis.[96]

CHAPTER 48

Cystic Fibrosis

Judith A. Voynow

Thomas F. Scanlin

INTRODUCTION

Cystic fibrosis (CF) is an inherited disease that has a high frequency in Caucasians. The disorder affects all exocrine glands, with symptoms involving the lungs and pancreas usually dominating the clinical picture. CF is challenging to diagnose and manage because of tremendous variability in the degree and pattern of involvement of organs in different persons and the burden of therapy to maintain health. This chapter focuses on the pathophysiology and management of CF. Our current understanding of the genetics and underlying molecular biology are highlighted. Recently, FDA-approved, highly effective oral CFTR modulators have become available to most patients. These new drugs have markedly improved CFTR function and clinical outcomes in most patients with severe mutations. The prognosis is improving. The majority of patients now live past the age of 18 years, and the median predicted age of survival is now in the late 40s. However, complications of the disorder due to established multiorgan disease persist and are addressed in this chapter. Finally, the approaches to develop therapies to correct mutant CFTR in those patients not responsive to the current CFTR modulators will be described.

GENETICS

CF demonstrates an autosomal-recessive pattern of inheritance. In the United States, the incidence of the disease is approximately 1 in 3000 in Caucasians, 1 in 10,000 in Hispanics, and 1 in 15,000 in African Americans,[1] and the incidence is being established in patients of Asian ancestry.[2] The frequency of unaffected heterozygote carriers of a CF mutation is estimated to be 1 in 26 in persons of Northern European ancestry.

CF is caused by mutations in a single gene named the *cystic fibrosis transmembrane conductance regulator* (CFTR). This gene was identified with an approach known as positional cloning, which permitted mapping of the gene without prior knowledge of the biochemical defect through use of polymorphic DNA markers. Following a series of molecular cloning experiments, which included “chromosome walking” and “jumping,” a candidate gene was identified. This “candidate gene” was proved to be the CF gene in 1989, largely through the discovery of a frequent mutation.[3,4]

The CF gene spans approximately 230 kb of DNA and contains 27 exons. The mRNA is 6.5 kb and is detected in a variety of tissues, including lungs, pancreas, and sweat glands, which are predominantly affected in pathogenesis of the disease. The deduced polypeptide was predicted to be an integral membrane glycoprotein containing 1480 amino acids (Fig. 48-1; see “Pathogenesis”). Several major and minor splicing variants in the transcripts have been described in individuals with and without CF. In most cases, however, the significance of the alternative splicing variants is not clear.

The most common CF mutation, and the first to be described, is a three-base deletion in exon 10 that causes a deletion of phenylalanine from position 508 (ΔF508 or F508del) of the CFTR glycoprotein. This mutation accounts for 66% of CF mutations.[5] However, more than 2100 CF mutations have now been reported (*www.genet.sickkids.on.ca*), and the list continues to grow. In addition, many benign sequence variations have been described. A listing of the most common mutations and their relative frequency is included in Table 48-1. The large number of mutations makes accurate detection of a satisfactory percentage of carriers extremely difficult, and carrier screening for the general population has not been recommended or implemented. Testing for 32 of the most common mutations is widely available; such testing detects approximately 90% of the carriers in Caucasians of Northern European descent. Newborn screening for CF is now established in all 50 states in the United States, but the methods employed vary from state to state.[6] In families with an affected individual and known mutations, prenatal diagnosis and carrier testing using direct detection of mutations is accurate and available. In families with a member diagnosed as having CF, but with undetected mutations, sequencing of the complete CFTR coding region and critical intronic regions also is now available to detect rare mutations.

PATHOGENESIS

Discovery of the gene responsible for CF and description of its product, CFTR, have provided the necessary foundation for understanding the pathogenesis of the disorder at the molecular and cellular levels. CFTR is an integral membrane glycoprotein of approximately 170 kDa that is expressed in epithelial cells of affected organs. CFTR contains 1480 amino acids, which are arranged in 12 transmembrane domains, 2 nucleotide-binding domains, and a putative regulatory domain (Fig. 48-1). The most common mutation, F508del, is a three-base deletion that causes deletion

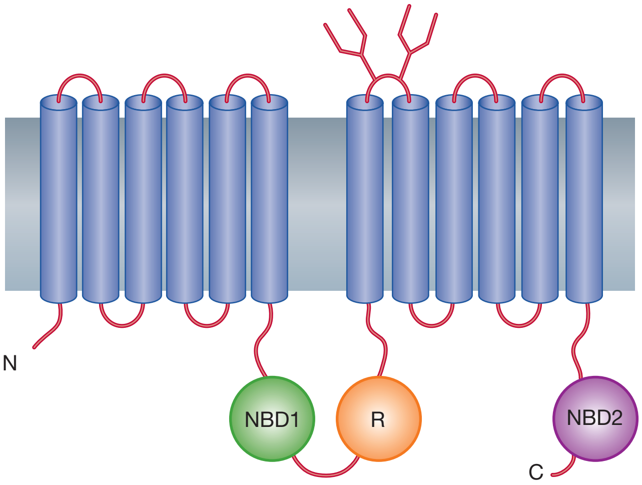

Figure 48-1 Domain model of the cystic fibrosis transmembrane conductance regulator (CFTR). Based on hydrophobicity plots, CFTR has 12 transmembrane-spanning domains, two nucleotide (N)-binding domains (NBD 1 and NBD 2), and a regulatory (R) domain. The 12 transmembrane domains form the ion channel “pore.” In the closed state, the “R” domain is believed to obstruct the channel. Channel opening requires binding of two adenosine triphosphates (ATPs) to the nucleotide binding domains. This model is similar to other ATP-binding cassette transporter proteins that bind ATP and transport ions or micronutrients. *(Reproduced with permission from Riordan J, Rommens JM, Kerem B, et al. Identification of the cystic fibrosis gene: cloning and characterization of complementary DNA. Science. 1989;245:1066–1073.)*

of phenylalanine from position 508, located in the proposed first nucleotide-binding domain. The original structural model, which was based on hydrophobicity plots, has proved to be essentially correct in its main features. CFTR shares many structural features with the "adenosine triphosphate (ATP)-binding cassette" transporter family, which includes P glycoproteins, as well as several bacterial transporters. CFTR has been clearly shown to function as an apical chloride channel in airway epithelial cells.[7]

The localization of CFTR to the apical aspect of airway epithelial cells and the role of CFTR as an apical chloride channel fits nicely with the simplest hypothesis to account for the pathogenesis of pulmonary disease in CF: Decreased secretion of chloride and water by airway epithelial cells results in dehydrated mucus. However, CFTR has other functions. CFTR transports bicarbonate;[8] loss of CFTR function results in acidification of the small intestinal lumen and in the airway lining fluid, causing mucus stasis.[9] CFTR regulates other ion channels, including the epithelial sodium channel. Loss of CFTR causes increased reabsorption of sodium; increased epithelium sodium channel activity alone alters regulation of ions and water, resulting in mucus obstruction of airways.[10] Alternatively, CFTR may also function in *intracellular* membranes (e.g., endoplasmic reticulum, endosomes, phagosomes, and clathrin-coated vesicles). Loss of CFTR localization or function in intracellular membranes may explain abnormalities of CF glycoproteins: increased sulfation of respiratory mucins, with decreased sialylation and increased fucosylation of both secreted and membrane glycoproteins.[11] Altered glycosylation of airway glycoproteins may significantly impact bacterial–epithelial interactions and innate immune functions in the lung.[12]

In addition to the effect of CFTR on epithelial ion channels and glycoprotein processing, loss of CFTR function negatively impacts pulmonary innate immunity.[13,14] Absence of CFTR function is associated with impaired bacterial killing both in vivo[15] and in vitro due to defective function of antimicrobials including human beta-defensin 1 and lysozyme.[16] CFTR also transports thiocyanate, a substrate required for lactoperoxidase activity; the loss of CFTR inhibits this antimicrobial.[17] Furthermore, in the CF airway milieu, macrophage function to resolve infection is impaired.[14] In addition, mucoid obstruction of airways, even in the absence of detectable infection, also activates neutrophilic inflammation.[18,19] Neutrophils have impaired phagocytosis in the CF airway, resulting in the release of neutrophil extracellular traps associated with high concentrations of neutrophil elastase in the airway.[20] In the CF airway, neutrophil elastase overwhelms the antiprotease capacity and has several proinflammatory activities.[21] Neutrophil elastase cleaves complement and immunoglobulins interfering with bacterial opsonization, upregulates respiratory tract mucins,[21] contributing to high airway mucin concentrations, and exacerbates protease injury by activating airway matrix metalloproteases.[22] CF airways have increased oxidant stress due to neutrophilic inflammation and reduced antioxidants, such as glutathione,[23] Together, these factors synergistically increase the inflammatory milieu in the airways in CF.

An impediment to progress in understanding the pathogenesis of CF lung disease was the absence of a completely suitable animal model. A number of mouse models of CF have been developed, and while these have been useful in understanding some features of the disease, such as the regulation of inflammation, a drawback has been the absence of spontaneous development of lung disease.[24] The development of CF ferret models[25,26] and CF pig models[15,27] has elucidated the mechanisms of some features of initial pathogenesis of CF.

CFTR mutations have been grouped into seven classes depending on the effect of the mutation on the expression, processing, and function of the protein (Fig. 48-2). The most common mutation, F508del, is a processing mutation (class II) in which very little of the mutant protein reaches the apical surface. In addition, if the mutant protein escapes lysosomal degradation and reaches the apical membrane, F508del protein has impaired ion channel function (a feature of class III mutations). Class III CFTR mutations localize to the cell membrane but lack ion channel function. Class I mutations are premature termination codon (PTC) mutations that decrease mRNA abundance and shorten mRNA half-life, resulting in minimal translation of CFTR protein. Classes I–III and VII constitute the most severe mutations of CFTR, while classes IV–VI are considered more mild mutations.

Class IV mutations have altered anion conductance through the channel pore; class V mutations have alternative splicing that impacts mRNA abundance; and class VI mutations have decreased channel protein half-life at the apical membrane. Class VII mutations fail to transcribe mRNA and will likely require CFTR bypass therapy.[28]

Recent insights concerning the mechanisms of these mutations have led to new highly effective CFTR modulator therapies for class

	Class I	Class II	Class III	Class IV	Class V	Class VI	Class VII
CFTR defect	No protein	No traffic	Impaired gating	Decreased conductance	Less protein	Less stable	No mRNA
Mutation examples	GLy542X, Trp1282X	Phe508del, Asn1303Lys, Ala561Glu	Gly551Asp, Ser549Arg, Gly1349Asp	Arg117His, Arg334Trp, Ala455Glu	Ala455Glu, 3272-26A→G, 3849+10 kg C→T	c. 120del23, rPhe508del	dele2,3(21 kb), 1717-1G→A
Corrective therapy	Rescue synthesis	Rescue traffic	Restore channel activity	Restore channel activity	Correct splicing	Promote stability	Unrescuable
Drug (approved)	Read-through compounds (no)	Correctors (yes)	Potentiators (yes)	Potentiators (no)	Antisense oligonucleotides, correctors, potentiators? (no)	Stabilisers (no)	Bypass therapies (no)

Figure 48-2 Classification of cystic fibrosis transmembrane conductance regulator (CFTR) mutations by molecular and biochemical abnormalities. This schematic depicts the effect of different classes of CFTR mutations on expression and function in the cell. Class I mutations block mRNA transcription. Class II mutations prevent normal CFTR protein processing and localization. Class III mutations permit CFTR localization at the apical membrane but inhibit chloride channel conductance. Class IV mutations result in partial chloride channel conductance. Class V mutations affect transcription, translation, or protein processing, resulting in reduced CFTR expression at the apical membrane. Class VI mutations cause increased turnover at the plasma membrane. Class VII mutations are due to large deletions in CFTR resulting in mRNA transcription failure. In the box below the figure, the mutant CFTR defect is described, examples of mutations in each class are provided, and the approach to corrective therapy and classes of drug therapies are listed. Class VII mutations will not be amenable to CFTR correction and potentiation because no RNA is generated; these patients will require CFTR bypass therapy.

II and III mutations (see "Treatment," below). Intensive research continues to focus on developing therapies for patients with class I and VII mutations and for rare mutations with too few patients for definitive clinical trials.

PATHOPHYSIOLOGY

In CF, all exocrine glands appear to be affected primarily, albeit to varying degrees. Because exocrine glands perform highly specialized functions in a variety of organs—for example, in the skin, respiratory tract, gastrointestinal tract, and reproductive system—the number of possible symptoms and complications in CF is large. Table 48-2 highlights the complications and symptoms of CF according to the age groups in which they most often occur. Obstruction of exocrine ducts by viscous secretions appears to play a cardinal role in the pathogenesis of almost all manifestations of the disease. In 10% to 20% of patients, the initial manifestation is often *meconium ileus*—that is, obstruction of the intestine by thick, viscous meconium stool. Chronic pulmonary disease, pancreatic insufficiency, and focal biliary cirrhosis progress gradually throughout the course of the disease, albeit at different rates in different patients. Progressive obstruction of exocrine ducts is a regular feature of the disease except in sweat glands, where obstruction of ducts has not been implicated in pathogenesis.

■ Respiratory Tract

In the lungs, hypersecretion of viscid mucus and chronic bacterial infection combine to produce a progressive and distinctive type of chronic obstructive airway disease that eventually leads to diffuse, severe bronchiectasis. The earliest pathologic lesions are found in the distal bronchioles. The viscid secretions are a primary defect due to mutant CFTR. This is supported by the demonstration in CF pig models of mucus tethered to submucosal ducts,[29] as well as failure of mucociliary clearance due to respiratory mucin adherence to airway epithelia.[30,31] Furthermore, the primary role of abnormal CF mucus in lung pathophysiology is also supported by evidence of muco-obstruction of airways in infants with CF, who have not yet developed any evidence of bacterial infection or structural injury of the airways.[19]

With the use of sophisticated culture methods, bacterial pathogens can almost invariably be isolated from the respiratory tract of patients with CF. The most common pathogens isolated from sputum cultures are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Less commonly found are *Escherichia coli*, *Klebsiella*, and *Hemophilus influenzae*. In later stages of the disease, *Pseudomonas* usually predominates. By adulthood, more than 70% of patients are colonized with *P. aeruginosa*. Chronic infection with *P. aeruginosa* elicits an anaerobic milieu within mucus plugs in the CF airway.[32] Using anaerobic culture conditions, large numbers of anaerobes, particularly *Prevotella*, *Veillonella*, and *Propionibacterium*, were detected in CF sputum but not in induced sputum from healthy volunteers.[33] There is a correlation between *Pseudomonas aeruginosa*–positive cultures and presence of the anaerobes.

Multidrug-resistant organisms (MDRO) are detected in CF sputum cultures with higher prevalence and chronicity. They are apparently

TABLE 48-2 Presenting Signs and Symptoms of CF

Infancy	Childhood	Adolescence/ Adult
Positive prenatal test for CF mutations or hyperechoic bowel on ultrasound	Pulmonary infection with *Staphylococcus* and *Pseudomonas*	Chronic bronchitis with bronchiectasis
Positive CF newborn screen	Malnutrition with steatorrhea and pancreatic insufficiency	Pansinusitis
Meconium ileus	Heat prostration with hypoelectrolytemia and metabolic alkalosis	Hemoptysis
Obstructive jaundice	Atypical asthma with clubbing and/or bronchiectasis	Recurrent pancreatitis
Edema with hypoproteinemia and hypothrombinemia	Esophageal varices and/or hypersplenism	Cholelithiasis
Failure to thrive	Nasal polyps	Chronic abdominal pain and constipation
Salty taste and/or salt loss syndrome		Obstructive apnea
Rectal prolapse		CF-related diabetes
Intestinal obstruction with or without intussusceptions/volvulus		Osteopenia
Recurrent pneumonia/ bronchiolitis		Chronic respiratory failure

associated with acute and chronic administration of antibiotics to suppress *P. aeruginosa*. These pathogens include *S. maltophilia*, *A. xylosoxidans*, and *B. cepacia complex*. Other opportunistic pathogens, including *Aspergillus* and nontuberculous mycobacteria, also have been detected more commonly in CF sputum cultures. It is challenging to determine whether these MDRO are actively contributing to CF lung disease or are commensal pathogens present in bronchiectatic airways.

Neutrophil-dominated lower-airway inflammation also plays a primary role in the pathogenesis of the characteristic central bronchiectasis of CF.[34] Bronchoalveolar lavage fluid (BALF) demonstrates increased neutrophils, neutrophil elastase, and various cytokines, especially IL-8, in infants with CF and detectable BALF infection compared with control subjects.[35,36] Importantly, in a prospective study of serial bronchoscopies and chest CT scans in infants diagnosed with CF by newborn screening, the presence of neutrophil elastase in BALF in infants with CF at 3 months of age is associated with risk for development of persistent bronchiectasis between 1 and 3 years of age.[37,38] Viral infections in infants with CF are associated with an increased risk for acquisition of *P. aeruginosa* infection and increased BALF neutrophils and cytokines.[39]

Typically, respiratory secretions increase when a patient with CF, already chronically colonized with *Pseudomonas*, develops a viral respiratory tract infection.[39] In turn, the increase in secretions leads to a gradual increase in cough and sputum production and then to an exacerbation of the pulmonary disease, usually manifested by increase in respiratory rate; retraction of the chest during inspiration; and diffuse, coarse inspiratory crackles. Leukocytosis is common. The chest radiograph demonstrates worsening hyperinflation. Both peribronchial thickening and nodular or cystic densities are more marked than usual. Pulmonary function tests show a worsening over baseline. Usually, residual volume (RV) increases; forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1) decrease; the forced expiratory flow between 25% and 75% of the exhaled vital capacity ($FEF_{25\%–75\%}$) also decreases. Treatment using antibiotics and chest physiotherapy generally succeeds in restoring most indices of pulmonary function to, or almost to, baseline. However, *Pseudomonas* and *Staphylococcus* often persist in sputum cultures.

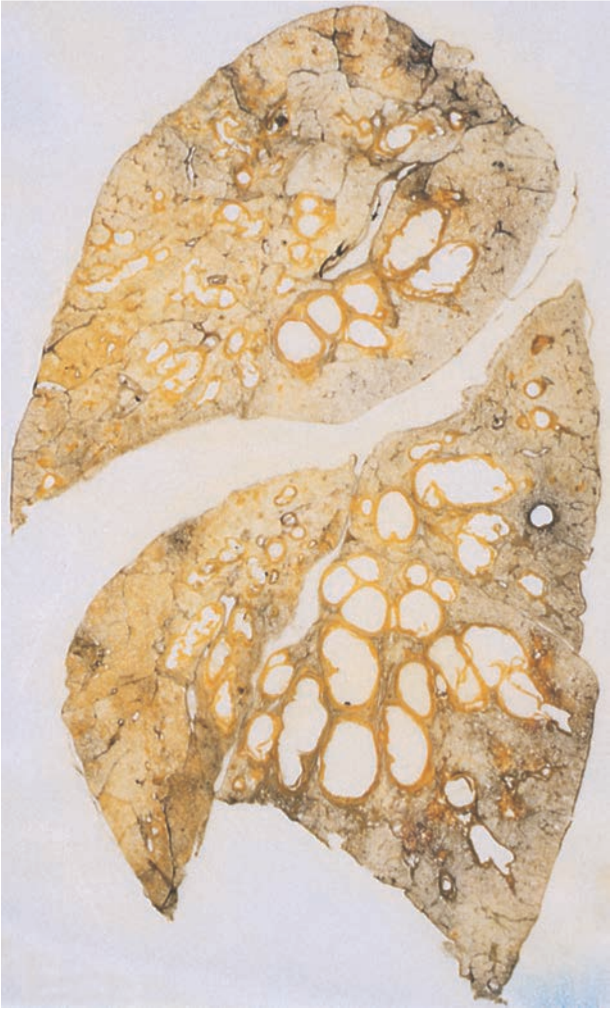

Figure 48-3 Section of lung from autopsy of a patient with CF, demonstrating remarkable dilation of large airways and preservation of intervening pulmonary parenchyma. *(Reproduced with permission from Dr. S. Moolten.)*

The most attractive hypothesis to account for the pattern of response to treatment is that therapy reduces the number and, probably, virulence of organisms. Despite the return to baseline after an exacerbation, however, the cumulative effect of repeated episodes is progressive bronchiectasis or atelectasis, or a combination of the two, accompanied by a gradual and irreversible decrease in pulmonary function. The striking degree of airway destruction and relative sparing of the pulmonary parenchyma at autopsy are shown in Fig. 48-3. A simplified scheme illustrating the evolution of the process is shown in Fig. 48-4.

■ Gastrointestinal Tract

As the average life expectancy of cystic fibrosis patients with CF has increased over the decades, gastrointestinal manifestations also have come to the forefront. Pancreatic insufficiency is one of the

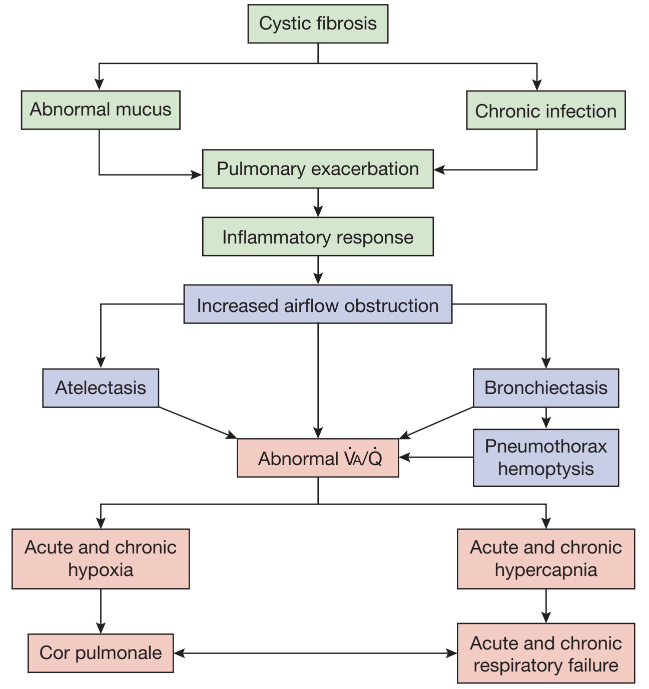

Figure 48-4 Simplified scheme for pathogenesis and progression of pulmonary disease in CF.

most recognized gastrointestinal manifestations of CF, though there are several genetic mutations that are characterized by pancreatic sufficiency.[40] Although pancreatic function may be either normal or abnormal at birth, it gradually becomes increasingly abnormal in most patients with CF, and about 85% of patients become pancreatic insufficient by 2 years of age.[41–43] As the pancreatic ducts become progressively obstructed by thick, viscous secretions from the exocrine portion of the organ, pancreatic enzymes that are trapped within the ducts lead to autodestruction of the pancreas. A cycle of destruction and obliteration of the ducts is set into motion, leading to cystic dilation of ducts proximal to sites of obstruction and fibrosis of the body of the pancreas. The term *cystic fibrosis* comes from the appearance of the diseased pancreas, characterized by cysts and fibrosis.[44] Pancreatic disease begins in utero,[45] and the degree of pancreatic insufficiency correlates with the class of CFTR mutations. Individuals with two severe mutations in classes I, II, III, and VI are at risk for earlier onset of pancreatic insufficiency. In advanced stages of the disease, pancreatic fibrosis sometimes causes obliteration of the islets of Langerhans and, consequently, diabetes. While typically described as the primary mechanism in diabetes development, this concept has been challenged by the notion that CFTR may have a direct effect on β-cell dysfunction as discussed in the next section.

The liver and biliary tract also are affected in CF. Hepatobiliary disease is thought to have a prevalence of about 30% and is now known to start in childhood. Gallbladder anomalies may be seen in about 24% to 50% of patients and include microgallbladder, gallstones, and gallbladder dysfunction.[46] Here also, the primary mechanism appears to be obstruction of small intrahepatic bile ducts by abnormally viscid secretions, leading to accumulation of toxic bile acids, depletion of hepatic antioxidants, and subsequent liver injury. CFTR is localized to the apical surface of the bile duct and gallbladder epithelium and not in the hepatocytes. Some newborn infants with CF develop the inspissated bile syndrome, characterized by prolonged obstructive jaundice starting at 2 to 8 weeks of age. The jaundice often clears without therapy. Gallstones and cholecystitis are, in part, secondary to hypokinesis of the gallbladder and affect a significant percentage of CF patients.[47,48] Interestingly, the stones are not cholesterol stones as they are in the general population, but rather pigment stones. This is thought to result from abnormal acidification of bile.

Cystic fibrosis–associated liver disease (CFLD) is now considered the third leading cause of death in CF patients following death from lung disease and from complications of lung transplantation. CFLD is more likely to occur in patients with class I to III mutations.[49] Other risk factors for liver disease appear to be male sex, meconium ileus, PiZ heterozygous state, and TGF-β1 polymorphisms. Over time, impaired secretion and deposition of viscous bile and its stagnation may damage hepatocytes directly. Asymptomatic elevations of liver enzymes (AST, ALT, and GGT) can be seen intermittently in 40% to 50% of patients with CF.[50] Hepatic steatosis is frequently seen[51] and may be related to malnutrition or deficiency of essential fatty acids, choline, and carnitine. Hepatic stellate cell activation stimulates the development of fibrosis, resulting in focal biliary cirrhosis. Multilobular cirrhosis and portal hypertension also are seen. More interest has been given to noncirrhotic portal hypertension characterized by nodular regenerative hyperplasia and obliterative venopathy secondary to luminal narrowing of the portal vein from smooth muscle hyperplasia.

There has been increasing interest in understanding the role of intestinal microbiota in the development of CF liver disease. The gut in cystic fibrosis patients is greatly affected not just by CFTR dysfunction, but also by chronic antibiotic exposures, CF-specific bacterial colonization, and increased luminal acidity and permeability.[52] The gut–liver axis via the portal vein likely plays a role in the link between altered gut microbiome and mucosal lesions and increased risk for cirrhosis.

The gut has a very high concentration of CFTR protein, so it is not surprising that this organ is greatly affected in CF. Within the gut, the duodenum has the highest CFTR mRNA levels.[53] Normally, the highest production of bicarbonate is found in the proximal intestines, quickly alkalinizing secretions from the stomach, allowing appropriate activation of pancreatic enzymes and micelle formation. The CF gut is characterized by decreased bicarbonate formation resulting in increased intraluminal acidity and increased viscosity of mucus, leading to malabsorption and bacterial overgrowth.[53–55] The CF gut is also known to have impaired motility. This may be secondary to high levels of prostaglandins and bacterial overgrowth rather than a direct effect of defective CFTR on smooth muscles.[56,57] As a result of abnormal mucus and motility, the most striking pathologic change in the intestines is hyperplasia of the mucous glands and goblet cells. Biochemical abnormalities in intestinal mucins may contribute to malabsorption of specific nutrients and bile acids. Much of the malabsorption in CF can be corrected by administration of pancreatic enzyme replacement therapy (PERT). However, the abnormal mucins may lead to slowing of intestinal transit time; the slowing, combined with maldigestion of food substances, sometimes causes fecal impaction in the terminal ileum and ileocecal area. This occurs in meconium ileus at birth and also in a condition referred to as *meconium ileus equivalent* or *distal intestinal obstruction syndrome (DIOS)* later in life. The fecal impaction, in turn, can cause volvulus or intussusception of the bowel (Fig. 48-5).

Rectal prolapse is a known, although not frequently noted, problem in CF.[58] Treatment of constipation and measures to reduce straining are usually sufficient to prevent continued prolapse.

Gastrointestinal malignancy is a growing problem, now that patients have increasing life expectancy; lifetime risk is increased 23-fold.[59,60] There are no formal recommendations regarding the timing of screening for colorectal cancers.

■ Endocrine Insufficiencies

A variety of endocrine disorders are well recognized in CF and are described below.

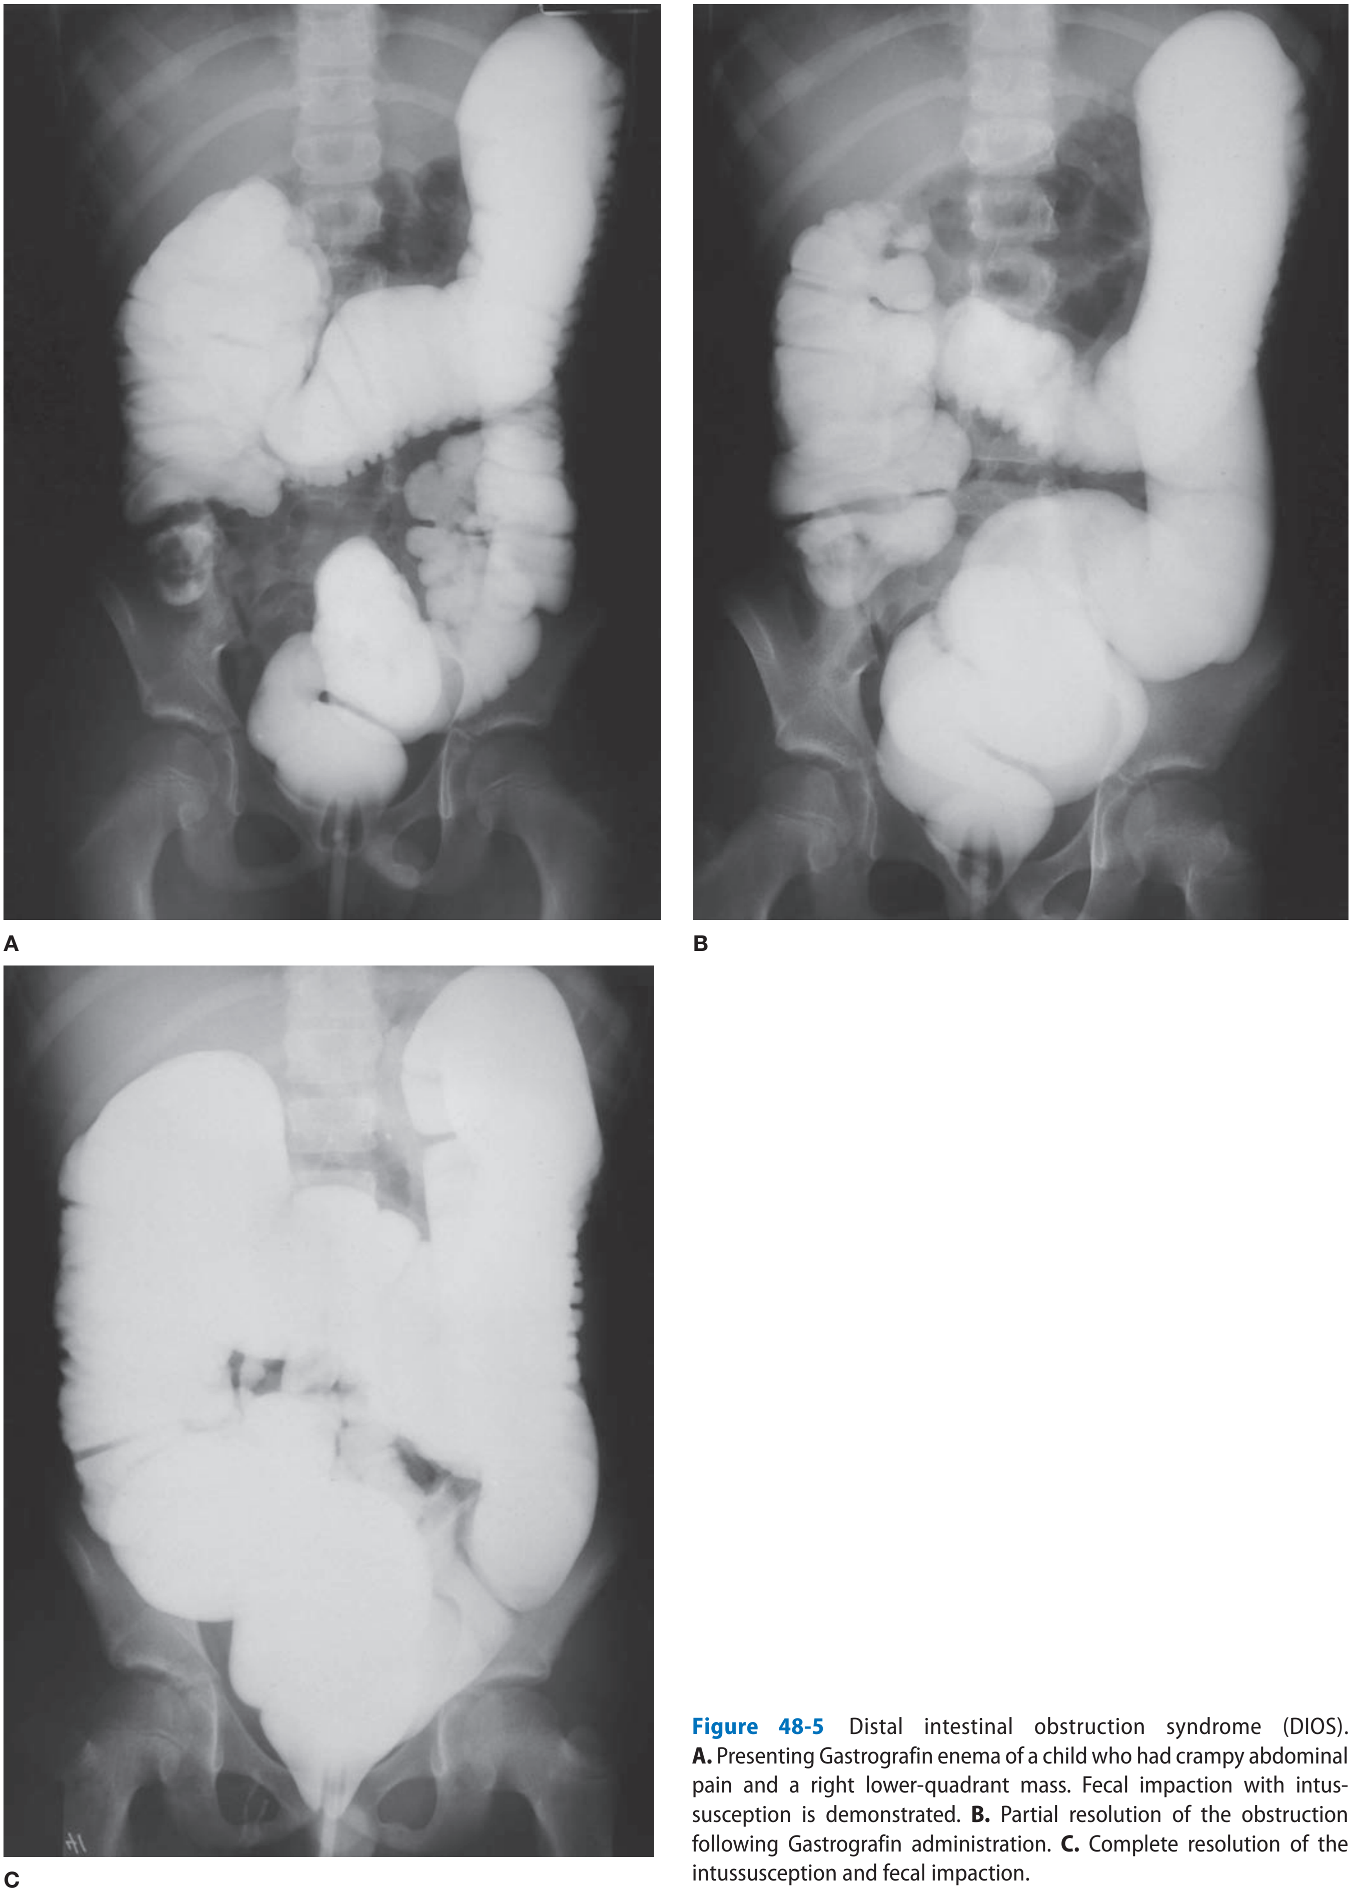

Figure 48-5 Distal intestinal obstruction syndrome (DIOS). **A.** Presenting Gastrografin enema of a child who had crampy abdominal pain and a right lower-quadrant mass. Fecal impaction with intussusception is demonstrated. **B.** Partial resolution of the obstruction following Gastrografin administration. **C.** Complete resolution of the intussusception and fecal impaction.

Cystic Fibrosis–Related Diabetes (CFRD)

Diabetes mellitus is a common comorbidity in CF, and it increases in frequency with increasing age. According to data from the University of Minnesota, where annual CFRD screening is recommended for all patients ≥6 years, CFRD affects 2% of children, 19% of adolescents, and 40% to 50% of adults with CF.[61] Similarly, CFRD was found in over a third of 775 patients age ≥6 years undergoing CFRD screening over a 15-year period.[62]

Underscoring its relevance, CFRD has been associated with decreased survival,[63–69] worse pulmonary function, and lower BMI.[68] Declines in pulmonary function and nutritional status have been observed even prior to CFRD onset.[67,70] Moreover, less significant glucose impairments are associated with greater declines in nutritional status over the previous year in children;[70] these findings suggest that more subtle glucose abnormalities may be clinically relevant in CF. One particularly relevant manifestation of impaired insulin secretion after the first 30 min of eating is compensatory late insulin secretion at 60 to 90 min that subsequently translates into postprandial hypoglycemia.[71,72] Microvascular complications such as retinopathy, nephropathy, and neuropathy also occur in CFRD but may be limited to those individuals with fasting hyperglycemia.[62]

Fortunately, early identification and treatment of CFRD appear to curb the impact of CFRD upon survival.[61] Insulin treatment of adults with CFRD without fasting hyperglycemia improves BMI,[73] and small studies have found that insulin treatment improves weight in children, even prior to development of CFRD.[74–76]

As described above, CFRD is considered an insulin-deficient state. In fact, delayed and blunted insulin secretion in response to a glucose load or meal prevail even in the setting of "normal" glucose tolerance in CF;[77–80] with oral glucose tolerance testing (OGTT), early insulin secretion defects are present for 1 h with glucoses as low as 155 mg/dL.[80,81] These abnormalities progress with worsening glucose intolerance.[77,79,82] This progressive decline in insulin secretion has traditionally been considered a product of "collateral damage" extending from obstructive damage to the exocrine pancreas.

This "bystander" model has been challenged in more recent years. Animal models suggest CFTR may play a more direct role in β-cell dysfunction.[83,84] For instance, CFTR knockout ferrets demonstrate glucose abnormalities and insulin secretion defects as newborns.[84] Islet inflammation also appears to directly impair insulin secretion in CF.[85] Additionally, disturbances in secretion/function of incretins, gut-secreted hormones that potentiate insulin secretion, have been described in CF[86] and in T2DM.[44–47,87–90] Moreover, the T2DM GWAS-implicated gene, *TCF7L2*, confers an even stronger risk of CFRD than T2DM while a genetic variant in *SLC26A9* appears to confer protection.[91–93] Initiation of therapy with the CFTR potentiator ivacaftor[94] for CFTR class III mutations is associated with improvements in insulin secretion during OGTT and acute glucose infusion, and resolution of[95] or less frequent progression to CFRD.[96] However, studies of the impact of lumacaftor/ivacaftor, a modulator therapy for patients homozygous for F508del, on glucose tolerance and insulin secretion are mixed.[97,98] The Cystic Fibrosis Foundation (CFF)-funded multicenter, longitudinal, observational Promise study will provide additional insight into the impact of highly effective modulator therapy on glucose excursion/tolerance and insulin secretion.

Cystic Fibrosis Bone Disease and Vitamin D Deficiency

Low bone mineral density occurs in as many as 40% of adults with CF, and with increasing life expectancy this comorbidity may become even more prevalent. The term *CF-related low bone mineral density* (BMD) is used to describe youth and adults with low bone densitometry or dual-energy x-ray absorptiometry (DXA)-derived measures of BMD, defined as BMD-Z score less than −2. The diagnosis of osteoporosis in youth and adults age <50 years requires low BMD-Z score and significant fracture, although the diagnosis can be made with just a vertebral compression fracture.[99,100]

The origin of osteoporosis in CF is multifactorial and is attributed to pancreatic insufficiency; malnutrition; poor growth; CFRD; deficiencies in vitamin D, vitamin K, and calcium; systemic inflammation; pubertal delay; exposure to glucocorticoids; skeletal muscle mass deficits; and decreased physical activity.[101] Bone histology in clinically stable CF adults is significant for decreased cancellous bone volume and decreased connectivity.[102] Importantly, the sequelae of low bone density in CF patients include increased risk of vertebral and rib fractures that is approximately twice as great as in the general population, and increased risk of kyphosis. With the aging CF population, additional data on risk of hip fracture, a typical osteoporotic fracture that occurs with aging in the non-CF population, is expected to emerge.

Individuals with CF are at increased risk for vitamin D deficiency, defined as 25-hydroxy vitamin D (25OHD) 20 to 30 ng/mL, and frank deficiency, defined as 25OHD <20 ng/mL. Vitamin D deficiency is due to malabsorption, as well as risk factors in the general population: low vitamin D–enriched diet, limited sun exposure, and use of sunscreen. Optimal vitamin D status has yet to be defined in either the CF or general population; CFF recommends 25OHD >30 ng/mL,[103] while the European CF guidelines recommend 25OHD >20 ng/mL.[100]

Reproductive Organs

Except for an increase in viscosity and an abnormal midcycle ferning pattern in cervical mucus, no consistent pathologic changes occur in the female reproductive tract in patients with CF. In the male reproductive tract, however, the vas deferens is either atretic or absent at birth. Although the pathogenesis of this lesion is not certain, viscous secretions may contribute to obstruction in utero, followed by failure of development of the vas deferens. Spermatogenesis and testicular development are otherwise normal. Because of either partial or complete obstruction of the vas deferens, approximately 98% of males with CF are aspermic.

Sweat Glands

The sweat glands of patients with CF manifest no distinctive histologic changes. Nonetheless, their function is abnormal. Micropuncture experiments have shown that the precursor solution secreted by the sweat glands is isotonic to plasma, both in CF patients and in normal subjects. In normal persons, as the sweat flows along the duct of the gland, sodium and chloride are reabsorbed, so that by the time that the opening at the skin surface is reached, sweat is hypotonic to plasma with respect to both sodium and chloride concentrations. In CF, the relative impermeability to chloride ions is thought to be responsible for the elevated chloride and sodium concentrations, which are the basis for the diagnostic test (the quantitative pilocarpine iontophoresis sweat test) and are also responsible for the characteristic increase in potential differences across isolated, perfused sweat glands from CF patients.

DIAGNOSIS

The diagnosis of CF requires the demonstration of abnormally high concentrations of sodium and chloride in the sweat of a person who has the characteristic history and symptoms of CF. The most prominent clinical features are chronic pulmonary disease and pancreatic insufficiency. The most compelling family history for the diagnosis of CF is a sibling with CF. If the clinical picture and/or the family history support the diagnosis, and if two sweat tests using the quantitative pilocarpine iontophoresis method are clearly positive, the diagnosis of CF can be made with assurance. Identification of two pathologic mutations, in addition to the characteristic clinical picture, is accepted as a criterion for the diagnosis. However, CF is a complex syndrome (Table 48-2), the clinical manifestations of which are sometimes subtle. In addition, the family history is not always straightforward. Therefore, a high index of suspicion, coupled with a battery of clinical tests, is sometimes required to establish the diagnosis, especially in adolescents or young adults.

Since CF occurs with a high frequency in the general population, the diagnosis should be considered routinely in a broad array of differential diagnoses. Although Table 48-2 categorizes symptoms according to the age at which they most often occur, these symptoms at any age should prompt consideration of the diagnosis of CF.

The most consistent feature of CF is an abnormally high concentration of sodium and chloride in sweat. Measurement of the chloride concentration is recommended for clinical testing. The only reliable sweat test is based on iontophoresis of pilocarpine, followed by quantitative determination of the concentration of chloride in an adequate, measured volume of sweat. Guidelines for the proper performance of a sweat test have been published.[104] In children, concentrations of chloride of <30 mEq/L are usually regarded as normal. However, the average of values for sodium and chloride concentrations are about 20 mEq/L for normal subjects and 95 mEq/L for those with CF. In children, values between 30 and 60 mEq/L are considered borderline elevated; such values call for further evaluation. As a result of recent experience with CF newborn screening, it has been suggested that sweat chloride values >30 mEq/L may be diagnostic in the first few months of life.[105]

The concentration of sodium and chloride in sweat increases gradually with age. Conditions other than CF in which the concentrations of sodium and chloride in sweat are abnormally high include malnutrition, adrenal insufficiency, hereditary nephrogenic diabetes insipidus, ectodermal dysplasia, and fucosidosis. Except in some instances of malnutrition, these conditions are readily distinguished from CF.[106] The finding of abnormal concentrations of sodium and chloride in sweat should automatically prompt evaluation of the patient to determine if, and to what extent, other organs are affected.

Genetic analysis can be used to confirm the diagnosis of CF. In patients with minimal symptoms, the diagnosis of CF can be made with certainty if two CF-associated alleles are present. As mentioned previously, screening for 32 of the most common alleles yields an overall sensitivity of 90% due to undetected alleles. Therefore, a negative mutation analysis does not rule out a diagnosis of CF, and atypical patients should be followed carefully.

Newborn screening is now established practice in the United States.[107] The initial stage of screening often uses the neonatal blood spot to determine the concentration of immunoreactive trypsinogen (IRT). If this is elevated, secondary screens vary in individual states from repeat immunoreactive trypsinogen determination to F508del or multimutation analysis. Next-generation sequencing is being introduced in addition to the IRT in a number of states.[108] The screening programs have a sensitivity that varies with the number of mutations included in the assay.[109] Risks versus benefits and the relative costs of the screening programs are being evaluated to determine the best approach.[110] Infants with positive newborn screens for CF are referred to CF centers for sweat test confirmation. It has been proposed that infants who have a positive newborn screen, but who do not otherwise fulfill the criteria for a diagnosis of CF,[107] should be termed as having "CFTR metabolic syndrome,"[53,111] or, in Europe, CFSPID (screen positive inconclusive diagnosis);[112] at a minimum they should be followed in a CF center until their status can be clarified. Another category for individuals with some, but not sufficient, features of CF is CFTR-related diseases.[113] These individuals were previously labeled as atypical or nonclassic CF. However, the comprehensive study of Miller et al. provides compelling evidence that we will need to reconsider the implications of being a carrier of a single CFTR mutation.[114]

CLINICAL EVALUATION

The evaluation of patients with CF includes chest radiography, tests of pulmonary performance, sputum culture, and assessment of pancreatic, endocrine, hepatic, and reproductive functions. Each is described below.

Chest Radiography

Rarely is the chest radiograph completely normal in CF. In the person with minor pulmonary symptoms, the manifestations may be questionable (e.g., mild hyperinflation and minimal peribronchial thickening). However, the radiographic findings become more distinctly abnormal as the disease increases in severity. Peribronchial thickening, which is often most prominent in the upper lobes of the lungs early in the course of the disease, usually progresses to affect all lobes. In the advanced stage of pulmonary involvement, ring shadows, cystic lesions, and nodular densities are increasingly apparent, as are areas of bronchiectasis and atelectasis. The central pulmonary artery often enlarges in the middle stages of the disease, but the cardiac silhouette remains within normal limits until the disease is far advanced. The variability in the chest radiograph is illustrated in Fig. 48-6 for three siblings with CF when each was 17 years old.

High-resolution computed tomography (HRCT) scans are more sensitive than plain radiographs. The most common abnormalities described are bronchiectasis, peribronchial thickening, mosaic perfusion, air trapping, and mucus plugging.[115] Early bronchiectasis is easily detected on the CT scan, even when routine chest radiographs are normal, as seen in Fig. 48-7. CT scan abnormalities may be detected prior to a change in pulmonary function tests. Chest CT scan abnormalities have been detected in asymptomatic newborn infants diagnosed by newborn screening.[116] Currently, there are no standard recommendations for CT use due to the radiation exposure incurred by these studies.

Pulmonary Performance

The lungs of patients with CF are usually morphologically and functionally normal at birth. Over time, accumulation of tracheobronchial secretions and recurrent infections progressively impair pulmonary function in almost all patients. In the fully developed clinical syndrome, all the pulmonary function abnormalities seen in chronic bronchitis, emphysema, and asthma may occur. However, one complicating regular feature of CF—bronchiectasis—modifies pulmonary performance. Chronic, local infection and airway damage increase the compliance of bronchiectatic airways, resulting in airway collapse during rapid expirations or cough. The usefulness of pulmonary function testing in CF is twofold: tracing the natural history of the disease and assessing the value of therapeutic interventions.

The earliest stages of the pulmonary disorder are the most difficult to quantify. In infants, tests are limited almost entirely to those that do not depend on the patient's understanding and cooperation. A variety of methods to measure infant pulmonary function have been devised; one method, the raised volume rapid thoracoabdominal compression technique, requires sedation of infants but provides values most similar to standard spirometry values, and has detected reduced pulmonary function in infants with CF.[117] The nitrogen multiple breath washout or lung clearance index can be performed in preschool-age children, detects early ventilation inhomogeneity that correlates with airflow obstruction by spirometry,[118] and has good positive correlation with CT scan changes.[38] After age 6 years, pulmonary function tests originally designed for adults may

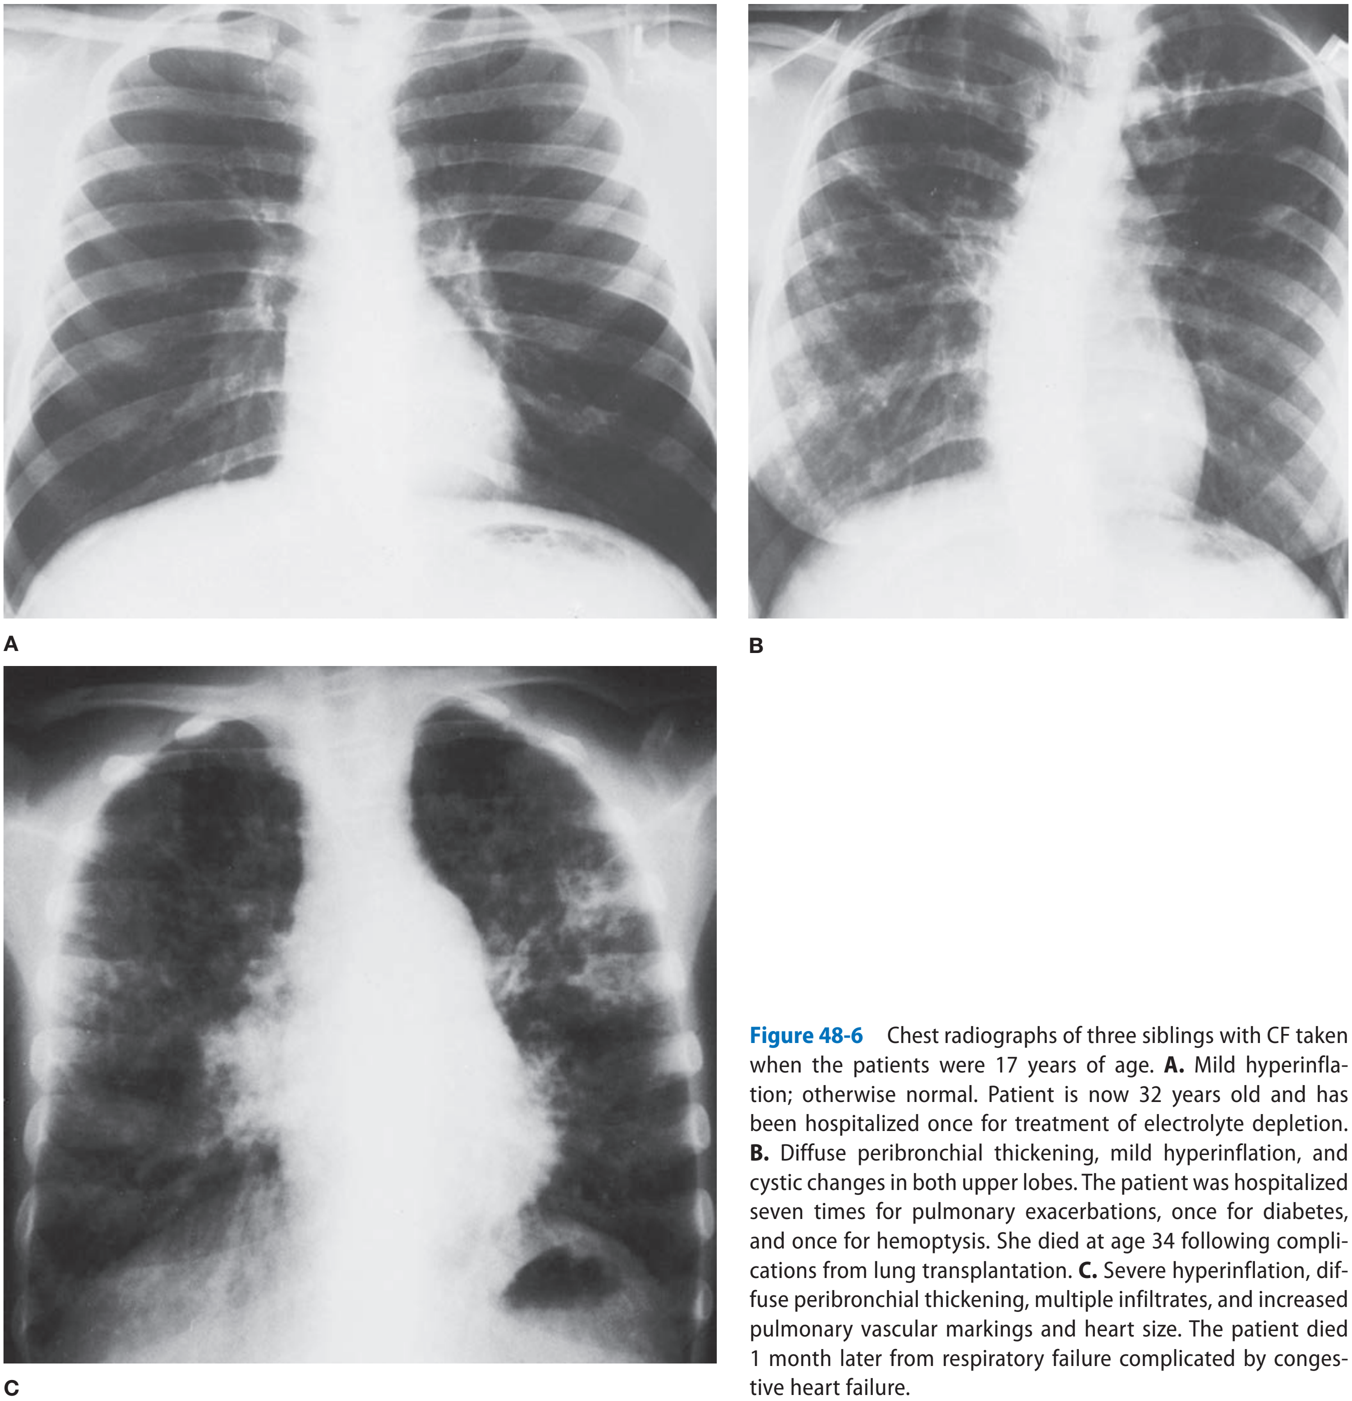

Figure 48-6 Chest radiographs of three siblings with CF taken when the patients were 17 years of age. **A.** Mild hyperinflation; otherwise normal. Patient is now 32 years old and has been hospitalized once for treatment of electrolyte depletion. **B.** Diffuse peribronchial thickening, mild hyperinflation, and cystic changes in both upper lobes. The patient was hospitalized seven times for pulmonary exacerbations, once for diabetes, and once for hemoptysis. She died at age 34 following complications from lung transplantation. **C.** Severe hyperinflation, diffuse peribronchial thickening, multiple infiltrates, and increased pulmonary vascular markings and heart size. The patient died 1 month later from respiratory failure complicated by congestive heart failure.

be performed quite readily on children. Changes in pulmonary performance throughout the natural history of CF can be described with confidence.

Obstruction in Small Airways

The small airways—that is, the bronchioles—are vulnerable to obstruction early in the course of CF. At this stage, as in cigarette smokers, results of tests for small-airway disease are apt to be abnormal, while those of tests for obstruction of large airways are still normal. Three factors interact in causing the obstruction: (1) intrinsic disease of the smaller airways, often in association with bronchiectasis in the proximal, larger airways; (2) viscid secretions, impaired ciliary action, and impaired cough; and (3) progressive decrease in lung elastic recoil.

The progressive reduction in lung elastic recoil in CF is predominantly a function of overinflation due to intrinsic airway disease, rather than loss of pulmonary parenchyma. This mechanism differs from that in chronic bronchitis and emphysema, in which the combined effects of parenchymal destruction and overinflation are responsible for the decrease in elastic recoil. Emphysema is not a regular feature of CF. In some patients, emphysema occurs only late in the course of the disease (Fig. 48-3).

Airway smooth-muscle tone increases only slightly in CF. Exercise elicits bronchodilation, followed shortly thereafter by bronchoconstriction. Both the bronchodilation and bronchoconstriction are far less impressive in CF than in asthma. Indeed, exaggerated bronchodilator responses in CF raise the possibility of superimposed asthma. In distinguishing between contributions to airway obstruction by intrinsic airway disease caused by CF and asthma, maximal expiratory flow-volume curves are sometimes helpful.

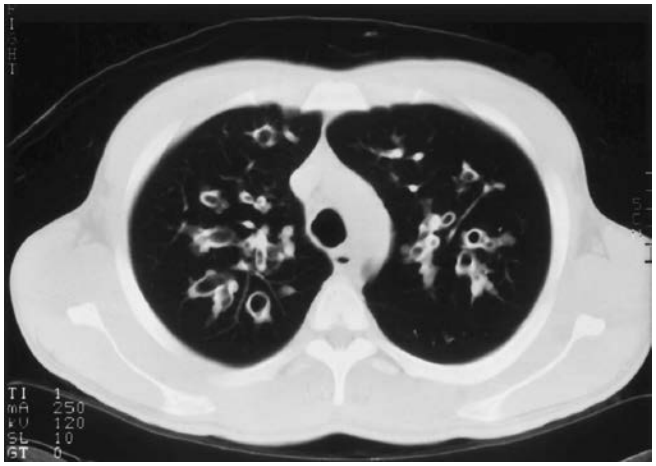

Figure 48-7 High-resolution chest computed tomography scan from a patient with CF. Marked bronchiectasis with peribronchial thickening is shown in the upper lobes.

Because of the bronchiolar locus of the early lesions in CF, abnormalities in breathing frequency–dependent tests (e.g., dynamic lung compliance), in volume-dependent tests (e.g., closing volume), and in maximal expiratory flow ($\dot{V}E_{max}$) at low lung volumes are demonstrable, even though results of tests of large-airway function (e.g., FEV$_1$ and airway resistance) are still normal.

Change in Lung Volumes

As with chronic bronchitis, emphysema, and asthma, RV in CF increases. Thereafter, an increase in functional residual capacity and, sometimes, in total lung capacity (TLC) is seen. Later in the course of the disease, air-trapping occurs, manifest as an elevated ratio of RV to TLC. This change decreases the compliance of the lung and increases the work of breathing.

Abnormalities in Gas Exchange

Early in the evolution of the pulmonary abnormalities in CF—that is, when tests of small-airway function alone are abnormal—ventilation-perfusion abnormalities usually result in widening of the alveolar-arterial oxygen gradient and an increase in the ratio of dead space to tidal volume (V_D/V_T). These abnormalities portend increasing inhomogeneities in alveolar ventilation and blood flow as the affected child grows to adulthood. The diffusing capacity for carbon monoxide (DL_{CO}) is low at rest and does not increase normally during exercise. This observation is difficult to reconcile with the preservation of the gas-exchanging surface of the lungs (in the absence of emphysema) until late in the course of the disease (Fig. 48-3).

As obstructive disease of the airways progresses and exaggerates the imbalances between alveolar ventilation and blood flow, arterial hypoxemia develops; pulmonary hypertension, cor pulmonale, and right ventricular failure follow, in turn. Late in the course of the disease, hypercapnia and respiratory acidosis contribute to the final picture of respiratory failure. At this juncture, the ventilatory response to inhaled CO_2 is depressed. Bouts of infection punctuate the course of the illness; during each episode, pulmonary function deteriorates, but it usually returns toward baseline, except in the preterminal stages of the disorder.

■ Sputum Culture

The unique respiratory flora isolated from sputum or oropharyngeal cultures from patients with CF is helpful in establishing the diagnosis and in guiding the antimicrobial therapy for acute exacerbations. In many patients with CF, *P. aeruginosa* and *S. aureus* are found alone, or in combination with other organisms, in the sputum. There is growing evidence of correlations between different organisms and CF lung disease progression. The presence of mucoid *Pseudomonas* is important because its acquisition predicts more rapid progression of CF lung disease.[119] Similarly, acquisition of methicillin-resistant *Staphylococcus aureus* is associated with a decline in pulmonary function[120] and worse survival.[121] Infection with the *Burkholderia cepacia* complex organisms may be aggressive with rapid deterioration of clinical status or may have an indolent course; the presence of mucoid-positive organisms appears to be protective.[122] Chronic antibiotic therapy to suppress *Pseudomonas* has improved clinical outcomes but has also led to a greater number of multidrug-resistant organisms identified in sputum, including *Stenotrophomonas maltophilia* and *Achromobacter xylosoxidans*. Chronic colonization with *Stenotrophomonas maltophilia* induces a serologic response and independently correlates with progression in airflow obstruction.[123]

In addition to bacteria, sputum cultures for detection of molds and nontuberculous mycobacteria are helpful to guide therapy for patients with acute exacerbations unresponsive to antibiotic therapy, or for patients with unexplained progression of lung disease. Allergic bronchopulmonary aspergillosis (ABPA) complicates CF lung disease,[124] and recent evidence suggests that *Aspergillus fumigatus* may also be associated with airway infection or allergy-triggered asthma in the absence of ABPA.[125] The prevalence of nontuberculous mycobacteria ranges from 7% to 24%, with the most frequent species identified as *M. avium* complex and *M. abscessus*.[126]

■ Pancreatic Function

The evaluation of pancreatic function is an important part of establishing the diagnosis of CF, since almost 90% of patients have pancreatic insufficiency. Infants with pancreatic insufficiency due to CF may present with failure to thrive and loose or frequent stools. However, visual appearance does not always correlate with the degree or presence of fat malabsorption. Most infants with CF are now identified early as a result of newborn screening. Currently, the diagnosis of pancreatic insufficiency can be made by measurement of fecal elastase 1 levels with the human enzyme-linked immunosorbent monoclonal assay (ELISA) for fecal elastase (FE). The fecal elastase 1 test is easier to perform than other studies for pancreatic exocrine function and requires a random single stool sample. It is easy to obtain in patients with CF and is not affected by the use of pancreatic enzyme replacement therapy (PERT). Of note, fecal elastase level can be falsely low if performed on loose stool; the sample must be at least semi-formed. The sensitivity and specificity of this test depends on what cutoff values are used. For example, a cutoff value of <84 μg/g stool has a sensitivity of 87.5%, specificity of 81.6%, PPV of 66.7%, and NPV of 93.9%.[127]

Also available is a polyclonal assay that detects human as well as porcine elastase, but it should not be used to diagnosis pancreatic insufficiency in patients already on pancreatic enzyme supplementation.

The gold standard for diagnosing steatorrhea is the 72-h fat collection; however, this test is cumbersome, requiring a 3-day period of high fat consumption with complete diary of food intake, and stool collection during the same time period for total stool fat analysis. Assessment of the degree of malabsorption is determined by the coefficient of fat malabsorption. There is some debate as to the value used for the diagnosis of pancreatic insufficiency. A malabsorption coefficient of greater than 7% is usually considered abnormal. Patients with CF usually have a malabsorption coefficient around 20% to 30%. The test is not popular with families who find the stool collections unappealing. Pancreatic stimulation tests are the most accurate measurement of pancreatic function but are invasive.

The Dreiling tube method, which required an oroduodenal tube placement for direct aspiration of pancreatic fluid following secretin or CCK administration, has been replaced by endoscopic fluid collection.[128] This method takes less time but does require anesthesia. The North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) recently published a position statement on the proposed protocol for this procedure.[129] Secretin-stimulated magnetic resonance cholangiopancreatography (MRCP)[130] and secretin-stimulated ultrasound, while measuring the degree of intraluminal duodenal filling, also are being used. Disadvantages of these methods are high cost and interobserver variability. They are also cumbersome and at this time are not clinically readily available.

Cystic Fibrosis–Related Diabetes

Because the onset of CFRD is generally insidious, and fasting hyperglycemia tends to be a late manifestation, annual CFRD screening with OGTT starting by age 10 years is recommended.[131,132] Based upon the fasting, 1-h, and 2-h plasma glucose (PG0, PG1, and PG2) during the OGTT, the following glucose tolerance categories are defined:

- Normal glucose tolerance (NGT) = PG1 <200 mg/dL and PG2 <140 mg/dL
- Indeterminate = PG1 ≥200 mg/dL but PG2 <140 mg/dL
- Impaired glucose tolerance (IGT) = PG2 ≥140 and <200 mg/dL
- CFRD = PG2 ≥200 mg/dL
  w/o fasting hyperglycemia (FH) = PG0 <126 mg/dL
  with FH = PG0 ≥126 mg/dL

Contrary to what one might expect, isolated impaired fasting glucose (PG0 100–125 mg/dL) is not associated with worse survival, nutritional status, or pulmonary function.[133] However, fasting glucose 110–125 mg/dL has been associated with progression to CFRD.[134] Over 10 years, fasting hyperglycemia occurs in 60% of patients with CFRD without FH at baseline.[62] At least in children, increased plasma glucose at 1 h during the OGTT predicts increased risk of progression to CFRD.[135]

Additional CFRD screening measures include fasting and postprandial glucose measurements during hospitalizations for acute illness.[131,132] Home glucose monitoring also should occur periodically during and after continuous overnight enteral feeds, as well as during intercurrent illnesses, intravenous antibiotic therapy, and glucocorticoid treatment.[136] While an elevated hemoglobin A1C (>6 >= .5%) is consistent with CFRD, the HbA1C tends to underestimate overall glucose intolerance in CF patients and is not generally recommended for CFRD screening.

Osteoporosis/Vitamin D Deficiency

Patients with CF are at risk for vitamin D deficiency and osteoporosis. Annual serum 25-hydroxyvitamin D levels should be monitored. In addition, the 2005 CFF guidelines recommend DXA scan to monitor bone mineral density in all adults and children greater than age 8 years with risk factors for osteopenia, including malnutrition, chronic glucocorticoid use, moderate to severe airway obstruction (FEV_1 <50% predicted), or history of fracture or delayed puberty.[101] Timing of additional DXA scans is informed by prior DXA and clinical course.[101] The more recent European CF Society guidelines recommend height adjustment of DXA-derived bone outcomes in youth with CF with growth or maturational delay;[137] robust reference data are now available to make these adjustments.[138,139]

Cystic Fibrosis–Related Liver Disease

Evaluation of liver function (transaminases, bilirubin, GGT) is an important part of the evaluation of CF. Transient elevations of serum transaminases can be often seen and may be related to intercurrent illnesses and medications. If levels of AST, ALT, GGT, and ALP are elevated, they should be repeated. The APRI (aspartate aminotransferase to platelet ratio index) has been found to be a marker of liver fibrosis.[140–142] The prothrombin time is sometimes prolonged, owing to a combination of malabsorption and decreased synthesis of clotting factors by the liver. Obtaining a PIVKA-II (protein induced by vitamin K absence II) level to assess vitamin K status can be helpful in these instances. However, these tests can often be relatively normal, even in patients with mild or moderate focal biliary cirrhosis. Liver ultrasound (US) is a useful screening tool that can identify steatosis, liver nodularity, cirrhosis, splenomegaly, and varices; however, it has low sensitivity. A liver US with Doppler may show reversal of portal blood flow in advanced disease with portal hypertension. According to a recent meta-analysis, US elastography can identify changes in liver stiffness[143] and is useful in identifying patients with precirrhotic liver disease. Once it has been established that the patient has advanced liver disease, screening endoscopy is necessary to assess for the presence of esophageal varices. Larger varices that are more likely to bleed can be banded. The mortality rate from an esophageal variceal bleed is about 30%.

Semen Analysis

Occasionally, a man who is found to have aspermia during an evaluation for infertility is found to have CF. In men with CF, a complete semen analysis is part of the evaluation. Azoospermia is found in more than 98% of men with the disorder.

Mutation Analysis

There are currently more than 2100 mutations associated with CF (*www.genet.sickkids.on.ca/cftr/*). A new initiative, The Clinical and Functional Translation of CFTR (CFTR2) (*www.cftr2.org*), funded by NIH, the US CFF, and Sequenom, is a website dedicated to publishing the functional implications of CFTR mutations. Patients homozygous for the most common mutation, F508del, have pancreatic insufficiency; patients with CF who have pancreatic insufficiency tend to have a worse prognosis. F508del is one of the major mutations classified as disease-causing; certain other mutations are associated with CF-related disorders, while some other mutations have no known clinical importance or are of unknown significance. Several mutations, including R117H, are associated with pancreatic sufficiency and a mild phenotype. Interestingly, the phenotype of R117H is linked to the expression of the polyT and polyTG intronic domains found 5′ to exon 9. A T5 polymorphism expressed with R117H results in congenital bilateral absence of the vas deferens (CBAVD) or idiopathic pancreatitis and may be complicated by mild lung disease. In contrast, R117H associated with T7 or T9 may have no manifestations of CF or CF-related disease.[144]

Certain alleles associated with CF (e.g., 3849 + 10kbC → T) are associated with nasal polyposis and bronchiectasis but normal sweat test results. The diagnosis of CF can be made with confidence in these patients. More problematic are persons with atypical presentations, normal sweat test results, and at least one CF-associated mutation. More extensive genotyping should be attempted for all patients with a high clinical suspicion for CF (see "Genetics," above), because mutation analyses will be used to determine eligibility for mutation-specific protein-correcting therapies. For example, therapy for CF patients with the G551D mutation using the CFTR potentiator ivacaftor results in astonishing improvements in respiratory tract symptoms, weight gain, and a shift from positive to borderline sweat chloride values[145] (see sections on Therapy, Genetics, and Future Directions).

Patients with the same genotype may have dramatically different phenotypes, supporting the concept that modifier genes play an important role in determining the CF phenotype. Three large GWAS consortia defined modifier genes associated with lung disease severity[146] and with specific disease manifestations, such as CFRD,[92] liver disease,[147] and meconium ileus.[148] Investigations using these large well-characterized cohorts recruited by the consortia have identified chromosomal regions of interest but have not yet confirmed gene targets or polymorphisms that confer increased risk of severe lung disease. Using a hypothesis-driven approach, several potential candidate modifier genes for severity of lung disease were identified, including α_1-antitrypsin, HLA antigens, nitric oxide synthase, mannose-binding lectin, transforming growth factor β (TGF-β), tumor necrosis factor α (TNF-α), and β_2-adrenergic receptor. However, none of these genetic polymorphisms was validated as a gene modifier by GWAS analysis in the combined consortia.

ATYPICAL CLINICAL PRESENTATIONS

Atypical clinical presentations confound the diagnosis of CF in adults; a high index of suspicion is required to establish the diagnosis. Approximately 6% of all CF is diagnosed after age 18 years. Late presentations of CF tend to occur in persons with pancreatic sufficiency; indeed, overweight or well-nourished persons may have CF. Recovery of unusual gram-negative organisms, mucoid *Pseudomonas* species, or *S. aureus* from sputum of asthmatics with persistent sputum production, chest radiographic abnormalities, or clubbing should prompt referral for sweat testing. Recurrent sinusitis and nasal polyposis may be the only manifestations of CF in a mildly affected person. Isolation of *P. aeruginosa* from deep nasal cultures should raise the suspicion of CF. Frequently, the sinus findings on CT mimic fungal sinusitis, demonstrating concentric, inhomogeneous material. Occasionally, persistent inflammation produces bony destruction that is mistaken for previous surgical intervention. Sweat testing and referral to a CF center should be considered for men with azoospermia or congenital bilateral absence of the vas deferens (CBAVD). The clinical entity "CFTR-related disease" has recently been defined by an international working group.[149] CFTR-related disease encompasses patients with evidence of CFTR dysfunction who do not meet the criteria for CF disease (for example, only one CFTR mutation, a normal sweat test, and single organ involvement). CFTR-related diseases include CBAVD, idiopathic pancreatitis, and diffuse bronchiectasis.[149]

TREATMENT

Intensive, comprehensive CF treatment programs designed to deal with specific symptoms, correct deficiencies, and prevent progression and complications of the disease have led to a dramatic increase in the median age of survival. Although the value of comprehensive treatment is beyond question, far less certain are the utility of each component of the treatment plan and the level of each component necessary for each patient. At present, the best approach appears to be determination of the type and degree of abnormality in individual patients and design of a treatment program that will improve or maintain function of the organ systems affected. Two recent reviews highlight the evidence supporting each component of CF therapy.[150,151] To ensure that the treatment regimen meets the needs of the individual patient, that necessary treatment is not omitted, or that side effects of prescribed treatments do not go unnoticed, it is often desirable to hospitalize the patient for diagnosis and evaluation. Hospitalization also provides an excellent opportunity for counseling the patient, parents, and family about the diverse aspects of the diagnosis, treatment, prognosis, and inheritance pattern of CF. Hospitalization provides the opportunity to monitor the response of individual patients to each component of the therapeutic program. Currently, the insurance requirement to demonstrate "medical necessity" often makes this option unfeasible.

An important aspect of the care of patients with CF is the network of more than 100 CF centers that exist throughout the United States and the larger network throughout the world. CF centers use a team approach to the care of patients. A CF care team ideally includes physicians, nurses, respiratory therapists, physical therapists, nutritionists, social workers, pharmacists, and genetic counselors. The current recommendation is that the patient meet with the CF team for an outpatient visit at least every 3 months for an evaluation of clinical status and for counseling to identify subtle changes in disease progression and to encourage adherence to therapy.

■ Management of Pulmonary Disease

Management of CF-related pulmonary disease can be divided into two broad categories: chronic maintenance therapy and management of acute exacerbations.

Chronic Maintenance Therapy

More than 90% of patients with CF die from respiratory failure or pulmonary complications. The goals of treating the pulmonary disorder in CF are to prevent and treat the complications of airway obstruction and infection. Although management of the pulmonary disorder consists of many components applied in combination,[152] the individual components of therapy are discussed separately below.

Chest Physiotherapy Almost all treatment programs for CF include a strategy intended to clear pulmonary secretions to prevent complications arising from airway plugging by viscous secretions. Chest physiotherapy—that is, "percussion and postural drainage"—performed regularly is the most widely prescribed method. In infants and young children, chest physiotherapy is generally performed routinely, twice daily. Percussion and postural drainage technique has been modified to exclude head-down positioning, which increased the risk of GE reflux and increased the duration of acute exacerbations of cough in infants.[153]

In addition to manual chest percussion and postural drainage, there are several other effective modalities for chest physiotherapy. These alternative measures include the high-frequency chest-wall oscillatory vest (HFCWO); the flutter device, a small pipelike device that produces an oscillating resistance during a forced expiratory maneuver; the Acapella and Aerobika devices that produce both positive expiratory pressure and an oscillating resistance during forced expiratory maneuver; positive expiratory pressure (PEP) mask; intrapulmonary percussive ventilation; autogenic drainage and active cycle of breathing; and exercise.[154]

Overall, due to the difficulty in designing unbiased, well-controlled trials with sufficient power to unequivocally distinguish efficacy between treatments, evidence does not exist to demonstrate superiority of one airway clearance mechanism over another. Therefore, the recommendations based on expert opinion are that airway clearance should be initiated in asymptomatic infants because they develop signs of lung disease within the first few months of life; and that patients should be offered and instructed in a variety of methods so that they can select the methods that they deem provide the most subjective benefit.[155] Some form of physiotherapy that is effective in mucus clearance is required daily because without chest physiotherapy, pulmonary function deteriorates.[156]

At present, most CF centers recommend that all patients with CF attempt to maintain clearance of pulmonary secretions with a method that is applied regularly (e.g., twice daily). An additional recommendation is that chest physiotherapy be applied more often during an exacerbation of the chronic pulmonary infection. Unfortunately, the recommendation of chest physiotherapy on a regular basis—a time-consuming and often arduous form of treatment—is difficult to implement without considerable support and encouragement from family and health professionals.

Mucolytics and Inhaled Hypertonic Saline Several different mucolytic agents have been tried over the years. One that has endured is N-acetylcysteine. In the test tube, this agent is quite effective in dissolving mucin components and in decreasing the viscosity of sputum from patients with CF.[157–159] Although some centers that have outstanding pulmonary outcomes have used this agent as a standard part of the chronic regimen as an adjunct to airway clearance therapy in CF, others have been reluctant to use it because of a lack of randomized controlled trials.[160] One CF center that has a track record of outstanding CF outcomes recommends using N-acetylcysteine in combination with sodium cromolyn and albuterol (W. Warwick, personal communication). We continue to recommend its use to our CF patients. Interestingly, N-acetylcysteine was found to activate CFTR Cl^- conductance in cultured epithelial cells.[161]

In 1994, Pulmozyme, a DNA-cleaving enzyme, was approved for use in patients with CF following a large, phase 3, multicenter trial.[162] Once-daily treatment maintains pulmonary function and decreases the relative risk of respiratory tract exacerbations in young CF patients with normal FEV_1 (≥85%).[163] Currently, this drug is in widespread use for CF. However, questions are currently being raised concerning duration of Pulmozyme use in the setting of administration of highly effective CFTR modifiers (see “CFTR Potentiators and Correctors,” below).

Abnormal homeostasis of airway surface fluid results in dehydrated secretions and impaired mucociliary clearance. As a strategy to improve airway surface hydration and airway clearance, inhaled hypertonic therapy was evaluated. In a large, randomized, placebo-controlled trial, patients with CF, age 6 years and older, inhaled 7% hypertonic saline twice daily following a bronchodilator for 48 weeks and had a significant reduction in the number of pulmonary exacerbations and days lost from school or work.[164] Although inhaled 7% hypertonic saline did not affect the frequency of pulmonary exacerbations in infants and children less than 6 years of age compared to control treated children,[165] in a subset of infants tested, infant pulmonary function testing revealed an improvement in $FEV_{0.5}$ in the hypertonic saline group—suggesting that this therapy may be useful and considered on an individual basis.[165]

Bronchodilators and Anti-inflammatory Agents Bronchodilators are often used in treating the pulmonary manifestations of CF. Their use should be individualized.[166] For example, in many patients, bronchospasm that is reversible with bronchodilators at one point in the course of the illness may prove refractory a short time later. In infants who are audibly wheezing, a bronchodilator can be tried. In older patients, pulmonary function testing provides a more objective and quantitative measure of bronchodilator effectiveness.

Corticosteroids have been used with good results in infants with severe obstructive airway disease that does not respond to antibiotics and bronchodilators and in patients with CF in whom the pulmonary disease is complicated by severe asthma or ABPA. Preliminary observations initially suggested that patients with CF would benefit from long-term administration of alternate-day corticosteroids, based on the presumption that corticosteroids would decrease the airway inflammatory response. However, in a large, placebo-controlled, multicenter trial of alternate-day corticosteroids administered in two dosage regimens (1 mg/kg and 2 mg/kg), the development of many side effects precluded a general recommendation for long-term corticosteroid treatment in CF.[167] Subgroup analysis led to the suggestion that patients with moderately severe obstructive airway disease and those with chronic *Pseudomonas* infection might benefit from treatment for periods of less than 1 year. Beneficial effects were sufficient to prompt further studies of anti-inflammatory agents in CF. A controlled 4-year trial of high doses of ibuprofen in 40 patients with CF showed improvement in the rate of decline of pulmonary function in children.[168] Questions remain whether side effects that might accrue with continued therapy will justify the gains. In concert, these two studies suggest that future development of a lung-specific anti-inflammatory agent with fewer systemic side effects may offer a promising approach.

Antibiotics Two major innovations using antibiotics have been implemented as part of the regimen of maintenance therapy for CF. First, inhaled therapies have been demonstrated to successfully eradicate initial *Pseudomonas* infection and postpone chronic colonization in three large prospective trials of patients with CF in North America and in Europe.[169–171] Second, chronic inhaled and/or oral antibiotic therapies successfully decrease the progression of lung disease related to chronic *Pseudomonas* infection. In addition to these therapies, it is important to emphasize that person-to-person transmission of *P. aeruginosa* and other opportunistic microbes is another source for chronic colonization. In health care facilities for CF patients, contact isolation precautions are recommended.[172]

Chronic airway colonization/infection with *P. aeruginosa* promotes progression of lung disease. Hoiby et al. championed early treatment of *P. aeruginosa*–positive sputum cultures with inhaled colistin and oral ciprofloxacin, even in the absence of symptoms, as a modality to prevent chronic colonization.[173]

The EPIC trial[169] tested four randomized regimens: cycled therapy vs. culture-driven therapy; and 28 days of inhaled tobramycin inhalation solution (TIS) in the presence or absence of 14 days of oral ciprofloxacin. Approximately 80% of patients remained free of *P. aeruginosa* for the duration of the study (18 months), with no difference concerning time to first pulmonary exacerbation attributed to regularly cycled therapy or the addition of ciprofloxacin.

The ELITE study[170] was an open-label, randomized study comparing 28 to 56 days of inhaled TIS; it revealed approximately 90% eradication at the end of therapy with 66% to 69% of patients having *Pseudomonas*-free cultures at the end of the 27-month study. Another trial comparing inhaled colistin and oral ciprofloxacin to inhaled TIS and oral ciprofloxacin showed no difference between regimens in eradication, with approximately 62% to 65% of patients having *Pseudomonas*-free cultures at 6 months.[171] Therefore, although the evidence from these three studies supports antibiotic eradication of new *Pseudomonas* infection, there is no consensus yet for a specific therapeutic regimen.[174]

Another approach that has been advocated is suppression of chronic *Pseudomonas* colonization by alternating monthly cycles of inhaled antibiotics. Inhaled, preservative-free TIS, 300 mg twice daily for 28 days on and 28 days off, improved pulmonary function (FEV_1 increased by 10%) at the end of the third treatment cycle (20 weeks) compared with placebo.[175] Recently, inhaled aztreonam, 75 mg three times per day, was tested in an open-label study of every other month regimen for patients with chronic *P. aeruginosa* infection.[176] Patients reported improved symptoms and pulmonary function during on-therapy months with sustained weight gain over the 18-month duration of the study.

Another antibiotic that has been studied as a chronic therapy in CF is oral azithromycin. Azithromycin, 250 mg or 500 mg thrice weekly, was evaluated in CF patients colonized with *P. aeruginosa*. After 6 months of therapy, patients on azithromycin had a modest improvement in FEV_1 (6.2%), increased weight gain, and decreased rates of pulmonary exacerbations.[177] Although macrolide antibiotics have been reported to have anti-inflammatory properties,[178] there is no direct evidence of azithromycin-induced anti-inflammatory activity in CF. One concern about inhaled tobramycin, inhaled aztreonam, and oral azithromycin as chronic therapies is the risk of bacterial resistance and selection for growth of MDRO. In addition, questions regarding selection of patients and timing and duration of treatment remain unanswered.

CFTR Potentiators and Correctors The most exciting breakthrough in CF therapies was announced in 2011 with the demonstration that an oral drug, ivacaftor, corrected the physiologic impact of a CFTR mutation, G551D. The G551D-mutant CFTR protein is expressed at the cell surface but does not conduct chloride or regulate other ion channels (class III mutation). Ivacaftor, a potentiator, increases the open probability of the CFTR channel to increase chloride conductance; this drug was discovered using a high-throughput screening approach.[179] In a phase 3, randomized, placebo-controlled, double-blind trial for CF patients with at least one copy of G551D mutation, ivacaftor, administered orally, 150 mg twice per day for 48 weeks, increased FEV_1 percent predicted by 10.6%, decreased risk of pulmonary exacerbations by 55%, improved CF quality of life (CFQL) respiratory symptom scores by 8.6 points, decreased sweat chloride values by 48 mmol per liter, and was associated with an average 2.7-kg weight gain.[145] Currently, other gating mutations similar to G551D and residual function mutations have been approved for ivacaftor therapy. Ivacaftor is approved for patients with CF at age 6 months and older.

Corrector and potentiator combination CFTR modulator therapies for F508del homozygous and heterozygous[180] include lumacaftor/ivacaftor (Orkambi),[181] tezacaftor/ivacaftor (Symdeko),[182,183] and triple therapy with two correctors and one potentiator: elexacaftor (ELX), tezacaftor (TEZ), and ivacaftor (IVA) (Trikafta). The corrector drugs function as chaperones to enhance intracellular processing of F508del, resulting in increased plasma cell membrane expression. These drugs were combined with the potentiator drug, ivacaftor, to increase open channel probability and improve chloride conductance.

Orkambi is FDA-approved for patients with two copies of the F508del mutation age 2 years and older. Symdeko is FDA-approved for patients age 6 years and older with two copies of the F508del mutation or one copy of F508del and one copy of one of 26 specified CFTR residual function or splice mutations. Trikafta is approved for patients with CF age 6 and older[184] who have at least one copy of F508del and a minimal function mutation.

Trikafta was compared with Symdeko in a phase 3, randomized, double-blind study of patients with CF homozygous for F508del.[185] After a run-in period of all patients on TEZ/IVA for 4 weeks, the ELX/TEZ/IVA group was compared with the TEZ/IVA group over an additional 4 weeks, and the ELX/TEZ/IVA group had a significantly greater increase in FEV_1 by 10 % predicted, greater decrease in sweat chloride concentrations of 45.1 mmol per liter, and improved CFQ-R respiratory domain questionnaire score of 17.4 points compared with TEZ/IVA alone.

Trikafta was investigated in a phase 3, double-blind, randomized, placebo-controlled trial for patients heterozygous for F508del and another minimal function CFTR mutation. In this trial, 403 subjects were randomized to drug vs. placebo over 24 weeks.[186] Patients treated with Trikafta compared with placebo had FEV_1 percent predicted 14.3% higher, rate of pulmonary exacerbations 63% lower, sweat chloride 41.8 mmol per liter lower, and better CFQ-R respiratory domain questionnaire score by 20.2 points.

The efficacy of these drugs to improve clinical status is so dramatic that studies are ongoing to determine whether standard therapies of airway clearance or nutritional therapies can be stopped when patients are on highly effective modulator therapies.

Management of Acute Exacerbations of CF Pulmonary Disease

During the past few decades of treatment of CF, antibiotics have proved to be the key element responsible for increased survival. A reasonable approach balances the dangers of overzealous administration of antibiotics against progressive airway damage and bronchiectasis resulting from untreated infection. The approach is based on sputum culture at the time of diagnosis and at regular intervals thereafter.

When signs and symptoms herald an exacerbation of pulmonary infection (i.e., increased cough or sputum production, dyspnea, decreased exercise tolerance, decreased appetite) or new abnormalities on the physical examination (i.e., increased respiratory rate, use of accessory muscles, changes on auscultation of the chest including decreased breath sounds, new crackles or wheezes, weight loss), new abnormalities on the chest radiograph, or a decline in pulmonary function tests, chest physiotherapy is increased and appropriate antibiotics are given orally—or for severe exacerbations, intravenously.

Currently useful agents for treating staphylococcal infections include dicloxacillin, cephalexin, the third-generation penicillin-clavulanic acid combinations, and macrolides. Ciprofloxacin, a quinolone derivative that can be given orally, is initially effective against many strains of *Pseudomonas* and has gained widespread use in the outpatient management of CF. A major disadvantage in its use is that resistance often develops after a few courses of treatment. A newer quinolone, levofloxacin, is often effective against both *Staphylococcus aureus* and *Pseudomonas aeruginosa*.

For treatment of a severe pulmonary exacerbation of CF caused by methicillin-resistant *Staphylococcus aureus*, vancomycin or linezolid are indicated. For *Pseudomonas,* a combination of an aminoglycoside given intravenously and a semisynthetic penicillin is generally used. This combination is presumed to act synergistically on *Pseudomonas*, and the *Pseudomonas* is less likely to become resistant to either antibiotic.

The antibiotic combination currently in wide use is tobramycin and piperacillin-tazobactam. In order to achieve high levels of antibiotics in the airways and in secretions, the aminoglycoside is generally administered in higher doses, 10 mg/kg/d instead of 7.5 mg/kg/d. A randomized trial comparing once-daily versus thrice-daily regimens of tobramycin revealed that once-daily IV therapy provides equivalent efficacy with less nephrotoxicity in children.[187] Dosing should be titrated for serum peak levels of 25 to 35 μg/L and trough levels of less than 1 μg/L.

The third-generation penicillins and cephalosporins piperacillin and ceftazidime, carbapenems such as imipenem and meropenem, and the latest beta-lactam, aztreonam, also are quite effective against *Pseudomonas.* When given alone, resistance often develops quickly. Usually, these agents are used in combination with an aminoglycoside. Because the sensitivity and resistance patterns of *Pseudomonas* often change, various combinations are tried at different times, with clinicians relying on sensitivities from recent isolates to determine which is most effective agent. For other resistant gram-negative organisms, such as *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, *Acinetobacter baumannii*, and *Achromobacter xylosoxidans,* other antibiotic combinations are indicated, including ceftazidime, meropenem, ciprofloxacin, minocycline, aztreonam, chloramphenicol, or trimethoprim/sulfamethoxazole.

Staphylococcus, *Pseudomonas*, and other gram-negative organisms, such as *B. cepacia*, *A. xylosoxidans*,[188] *Acinetobacter baumannii*,[189] and *S. maltophilia*, once present on sequential sputum cultures, are difficult to eradicate. However, most other manifestations of an exacerbation of pulmonary disease abate during a 2-week course of antibiotics administered intravenously; for example, the densities seen on the chest radiograph decrease, the white blood cell count decreases, fever and respiratory rate decrease, and pulmonary function test results, which often deteriorate at the start of an exacerbation, return to their previous baseline. Although many patients begin to show improvement after 5 to 7 days, most CF centers continue antibiotics intravenously for at least 2 weeks to decrease the relapse rate and to prolong the interval between exacerbations. Indeed, some centers routinely recommend a 3- to 4-week course of intravenous antibiotics to treat an exacerbation of a pulmonary infection. Although most clinicians and the existing guidelines[190] are in agreement that increasing airway clearance and giving systemic antibiotics to cover the patient’s known pathogens are the most important elements to treat a pulmonary exacerbation in CF, there are no evidence-based guidelines on the use of steroids. However, if the patient is known to have a component of asthma to their lung disease, it is our practice as well as that of others to give a 5-day course of steroids 1 to 2 mg /kg in pediatric patients or 60 mg/day in adults. In the occasional hospitalized patient who experiences a relapse or manifests an increase in symptoms shortly after administration of intravenous antibiotics is stopped, long-term intravenous administration of an aminoglycoside can be continued with use of a heparin lock. This technique may be helpful in allowing the patient to return home while still receiving effective doses of aminoglycosides. While the 14-day course of IV antibiotics is referred to as the "gold standard," it is unclear whether a 10-day course is sufficient and if a 21-day course is either necessary or superior. The STOP 2 trial is underway to provide data to answer these questions (*clinicaltrials.gov/ct2/show/NCT02781610*).

When patients are either not improving or are deteriorating with standard treatment, other possibilities such as a new pathogen, APBA, and CFRD have been ruled out, and the sole pathogen is MDR *Pseudomonas aeruginosa*, treatment options are limited. There are anecdotal reports of patients responding to phage therapy[191] as an alternative to antibiotic therapy. A clinical trial is underway to evaluate this approach in CF patients. *Pseudomonas aeruginosa* possesses a remarkable capacity and a plethora of mechanisms to develop resistance to antibiotics.[192] Many of these pathways present novel targets to develop alternative therapies such as lectin and glycopeptide blockade,[11,12] but they remain to be fully explored. It was hoped that synergy testing would provide a solution to treat MDR *Pseudomonas aeruginosa*, but a large clinical trial did not find an advantage to synergy testing.[193] It has been suggested that employing alternative methods of synergy testing may yet prove useful.[194]

■ Nutritional Support

Patients with CF should have detailed nutrition assessment at diagnosis and annually per the CFF guidelines.[195] Nutritional status should be screened at every visit. Patients are prescribed a high-calorie balanced diet. The CFF recommends that for infants and young children (0–2 years) weight for length be maintained at the 50th percentile and that children and adolescents (2–20 years of age) have their BMI percentile at the 50th percentile.

Although it is true that pulmonary function is the predominant factor in determining morbidity and mortality in CF, it is becoming increasingly clear that overall patient status is closely tied to nutritional status. Importantly, achieving and maintaining normal nutritional status is associated with maintenance of lung function in young children and adults. Calorie goals are often 110% to 120% of usual calorie requirements. At these caloric intakes, protein intake is often adequate to meet needs. Patients are encouraged to achieve calorie goals by the ingestion of calorically dense foods. If this is hard to achieve, calorie boosters (vegetable oils, butter, cheese) are recommended followed by the use of high-calorie supplements (shakes). Calorie needs may be increased in patients with chronic lung disease, malabsorption, and chronic liver disease. Nocturnal nasogastric feeds maybe used in the short term for aggressive nutritional rehabilitation, and patients who need long-term support have placement of a gastrostomy tube for ease of care. Usually, standard formulas are used but some patients with feeding intolerance and poor weight gain benefit from hydrolyzed formulas. Intravenous or parenteral nutrition is rarely used but may be required in patients who have had GI surgery.

Pancreatic status (insufficiency or sufficiency) should be determined and monitored as needed. The mainstay in managing the pancreatic insufficiency of CF is pancreatic enzyme replacement therapy (PERT), which consists of enteric-coated capsules containing amylases, proteases, and lipases. PERT should be ingested before meals that contain protein, fat, or complex carbohydrates. Dosing guidelines have been developed by the CFF. Fibrosing colonopathy or the development of colonic strictures is a complication that appears to be related to high PERT doses exceeding 10,000 lipase units/kg/day and was first noted following the introduction of high-potency pancreatic enzymes.[196] Most patients can be managed with pancreatic enzyme doses within the published guidelines. Patients who require higher pancreatic enzyme doses should be evaluated by a dietitian and a pediatric gastroenterologist.

Patients with pancreatic insufficiency are at risk for fat soluble vitamin deficiency. Guidelines also exist for vitamin supplementation, and CF-specific vitamin products are available.[195] It is recommended that fat-soluble vitamin status be monitored yearly, and additional supplements (D) may be required if levels are still low. It is very unusual for patients with CF to be vitamin A deficient if they are on a CF-specific vitamin preparation. Supplemental salt is needed by patients to prevent salt depletion. Salt is added to infant formula, and children and adults are encouraged to salt their foods liberally and to take salt-containing liquids and snacks during hot weather and periods of increased physical activity.

■ Management of Cystic Fibrosis–Related Diabetes

Insulin is the treatment of choice for CFRD, and ideally the regimen is customized to fit the needs of the individual patient. Combinations of basal (long-acting) and bolus (rapid-acting) insulins are used in the treatment of CFRD with fasting hyperglycemia. In the absence of fasting hyperglycemia, pre-meal rapid-acting insulin is the main treatment approach. Frequent meals, snacking, and "grazing" are not uncommon in CF, and the requirement of multiple daily injections can be prohibitive for some individuals. The insulin pump offers flexibility and can negate the need for frequent injections.[197] Moreover, calories are not restricted in CFRD although either avoidance of foods of low nutritional value (sugared soda or confections) or their consumption in combination with complex carbohydrates, protein, and fats is useful in avoiding excessive hyperglycemia. Pancreatic enzyme replacement also appears to improve meal-related glucose excursion.[86]

The role of treatment of pre-diabetes and early insulin deficiency in preserving pancreatic β-cell function, pulmonary function, and nutritional status has yet to be defined. However, while not formally assessed during a clinical trial, avoiding rapid-acting sugar consumption can mitigate the postprandial hypoglycemia that occurs in the setting of early/indeterminate glucose tolerance. Occasionally, prandial rapid-acting insulin is required to minimize the hyperglycemia that frequently occurs in the first 60 min after meal consumption, the subsequent robust insulin secretion, and the ensuing hypoglycemia 3 h after a meal.

■ Management of Cystic Fibrosis–Related Bone Disease and Hypovitaminosis D

Identification of CF bone disease (CFBD), in the absence of nontraumatic vertebral fracture, relies on the measurement of bone mineral density (BMD) by DXA. The 2005 CFF guidelines, developed before robust pediatric data were available,[138,139,198,199] recommend that baseline hip and lumbar spine DXA be obtained at 18 years and whole-body and lumbar spine DXA as early as age 8 years in the setting of risk factors including poor nutritional status or pulmonary function (FEV_1 percent predicted <50), excessive systemic glucocorticoid exposure, history of fractures, or delayed puberty.[101] In contrast, the 2011 European guidelines recommend baseline DXA by age 8 to 10 years.[100] DXA is then repeated at varying intervals depending upon the previous DXA and illness course: BMD-Z >-1 (every 5 years), <-1 but ≥-2 (every 2–4 years), and <-2 (yearly). Shorter stature and delayed puberty make interpretation of DXA in youth challenging. As a result, height-age-Z adjustment or use of bone mineral apparent density[138,139] is recommended, but how these perform in CF and their relationship to fracture risk remain unknown.

Healthy lifestyle, optimizing pulmonary function, nutritional status and vitamin D, vitamin K, and calcium supplementation, as well physical activity are all mainstays of preventing and treating CFBD. More aggressive treatment with bisphosphonates is recommended in youth for vertebral compression fractures or BMD-Z ≤−2 and significant fracture, prolonged systemic glucocorticoid use, or transplant. Criteria for pharmacologic intervention in young adults is less stringent: low trauma fracture, or BMD-Z ≤−1.5 and prolonged systemic glucocorticoid use or transplant, or BMD-Z ≤−2 and increased bone loss (≥4%). The pharmacologic arsenal for osteoporosis treatment is expanding, but medications like denosumab, a monoclonal antibody that inhibits bone resorption, and anabolic parathyroid hormone (PTH)-related therapies have received limited attention in CF and are not without potential side effects.[200,201] Thus, they are generally reserved for cases in which bisphosphonates are ineffective or contraindicated.[200]

The CFF recommends monitoring 25-hydroxyvitamin D annually and more frequently (every 12 weeks) to monitor response to more aggressive supplementation initiated for suboptimal status.[202] Limited data are available to inform guidelines for cholecalciferol (vitamin D_3) supplementation: in infants, initial dose 400 to 500 IU daily and, if subtherapeutic, up to 800 to 1000 IU daily; children aged 1 to 10 years, initial dose 800 to 1000 IU daily, if subtherapeutic, up to 1600 to 3000 IU daily, and if again subtherapeutic, up to 4000 IU daily; and children age >10 years and adults, initial dose 800 to 2000 IU daily, if subtherapeutic, up to 1600 to 6000 IU daily, and if again subtherapeutic, up to 10,000 IU daily. Consultation with a specialist is recommended if adequate 25-hydroxyvitamin D cannot be achieved with these maximum doses. Cholecalciferol 50,000 IU weekly is an alternative strategy used by specialists for individuals in the general population and may be leveraged for people with CF with appropriate monitoring.

NATURAL HISTORY AND PROGNOSIS

A comprehensive treatment program for CF has unequivocally improved overall survival of patients. Fifty years ago, the median survival was only a few years of age. For the 5-year period from 2015 to 2019, the median predicted survival was 46 years of age (CFF Patient Registry, 2019 Annual Data Report, Bethesda, MD). However, because CF is a complex disorder that affects different organs to different degrees, it is difficult to describe a "typical course" for a patient with CF. Some patients die in childhood or adolescence, while others survive well beyond age 50 years.

An important determinant of the natural history of CF is the severity of the pulmonary disease and the rate at which it progresses. Although most patients' conditions improve in response to therapy, skillful management does less to influence the course of the severely affected than that of the mildly affected patient.

A variety of scoring systems have been devised for CF. The clinical scoring system devised by Shwachman and Kulczycki, and the chest radiograph scoring system devised by Brasfield and associates, were widely used. However, although these and more elaborate scoring systems are useful in categorizing patients according to the severity of illness, none has proved useful in prognosticating the course of an individual patient.

Because CF is a genetic disease, the question of a familial pattern of severity is often raised. Figure 48-6 shows chest radiographs of three siblings with CF; the radiographs demonstrate mild, moderate, and severe disease in individuals in the same family. The capsule histories, which are included in the figure legend, also illustrate the variability in courses experienced.

Patients with CF can be categorized not only with respect to severity of illness, but also by survival. For example, more than half of patients with CF who underwent surgery for meconium ileus before 1965 died in the first 2 months of life. Although this situation had improved markedly by 1976, the survival rate for patients with meconium ileus was still not as good as for all other patients with CF. In addition, the survival rate was much lower for females than for males, especially in adolescents. In recent years, differences between the patients in these groups have declined or disappeared. Because of improvements in the collection of mortality statistics, comparison of current data with those from previous years may be somewhat misleading, Median predicted age of survival is now reported annually for the USA by the CFF. However, there is a difference in outcomes among individual CF centers, and since 2005, the CFF makes selected clinical outcome data for each US CF Center publicly available on their website (www.cff.org). It is hoped and anticipated that survival statistics will improve at a more rapid rate following the introduction of highly effective CFTR modulators in the six years since 2013.

COMPLICATIONS

The course of CF is often characterized by a gradual decrease in pulmonary function, punctuated by further abrupt declines during exacerbations. Malnutrition, when present despite therapy, often correlates best with the severity of the pulmonary disease. However, the course of CF may be suddenly altered by certain complications of the disease.

■ Hypoelectrolytemia and Metabolic Alkalosis

Hypoelectrolytemia and metabolic alkalosis are serious complications that are especially apt to occur during periods of hot weather, when losses of sodium and chloride increase. Electrolyte depletion may be life-threatening, especially in infants and young children (Table 48-3). Prompt fluid replacement with isotonic saline is critical.

■ Intestinal Obstruction

Intestinal obstruction in patients with CF may be related to DIOS, volvulus, intussusception, and adhesions from prior surgery. Acute or chronic crampy abdominal pain can be seen in patients with CF with pancreatic insufficiency and pancreatic sufficiency. This is most often due to DIOS, which is related to intestinal dysmotility, poor hydration of intestinal contents, and malabsorption. Typically, the pain is in the right lower quadrant of the abdomen and is related to a build-up of stool in the terminal ileum, cecum, and ascending colon. Treatment consists of adequate fluid and electrolyte intake, use of polyethylene glycol solutions, and treatment of malabsorption. If the obstruction is incomplete and manifested solely by a tender right lower-quadrant mass, then the previously described measures are used. Nasogastric infusion of polyethylene glycol solutions is also used successfully in the hospitalized patient. If these measures are unsuccessful or the patient has an obstruction, then

TABLE 48-3 Hypoelectrolytemia and Metabolic Alkalosis in Two Cystic Fibrosis Patients

	Serum Electrolytes, mEq/L				
Patient	Na	K	Cl	CO_2	Serum pH
No. 1	123	2.2	49	48	7.60
No. 2	125	2.4	55	41	7.63

hyperosmolar contrast enemas are administered by a radiologist after hospitalization is required. It is important that patients are well hydrated, that the terminal ileum is cleared of stool, and that an abdominal radiograph is performed to document clearance of stool prior to the patient being discharged from the hospital. Adherent stool/mucus may serve as the leading edge for a volvulus or intussusception (Fig. 48-5), and surgical consultation may be required. Careful pre- and postoperative management is essential to avoid the deterioration in pulmonary function that may follow the use of anesthesia.

Liver Disease

Liver disease is often asymptomatic and requires a high index of suspicion to detect. It can be diagnosed by evaluation of liver function tests on routine yearly studies given lack of evident laboratory markers. AST and ALT level should be monitored annually, as they can be elevated. Other important parameters to assess are a drop in platelet count over time (even if it is within normal laboratory range), elevated GGT, palpable hepatosplenomegaly, and abnormal echotexture of the liver on a liver US.[50] Other laboratory values that indicate compromised liver function are low albumin level, elevated bilirubin, and elevated INR, but these usually indicate advanced liver disease.

Assessment of liver status (synthetic function) and anatomy (abdominal US with Doppler) are important in the diagnosis of cirrhosis and portal hypertension. Only a small percentage of patients with significant liver disease will need liver transplantations, unlike in other chronic liver diseases seen in children. Liver biopsy is recommended in patients in whom an etiology other than CF-related liver disease needs to be established.[48] It is recommended that other causes of liver disease be ruled out and that patients receive hepatitis A and B immunizations.

There is a paucity of data and no strong evidence to support the routine use of ursodeoxycholic acid in patients with CF-related liver disease.[203–205] However, this medication is often used in doses of 10 to 20 mg/kg/day[206] as a choleretic agent to improve bile flow. Ursodeoxycholic acid does not help with gallstone prevention, since the main component of gallstones in CF patients is not cholesterol.

Persistent hepatomegaly or splenomegaly, or complications of portal hypertension, establish significant liver involvement. Patients may develop esophageal varices as a result of portal hypertension and present with upper gastrointestinal bleeding. Once bleeding has been identified as due to varices and hemoptysis has been excluded, therapeutic endoscopy (sclerotherapy or band ligation) must be performed. These procedures as primary prophylaxis are still controversial in pediatrics,[207] although it seems to be favored and is practiced frequently.

For adult CF patients, primary endoscopic prophylaxis is standard of care.[208] For patients with complications of portal hypertension, transjugular intrahepatic portosystemic shunting (TIPS) or surgical portosystemic shunts (splenorenal) can effectively decompress esophageal varices by decreasing portal pressure as a bridge to liver transplantation.

Of interest is how CTFR modulators affect liver function and influence CF-related liver disease. There are increasing number of reports that suggests that modulators such as ivacaftor improve liver disease.[209,210]

Liver transplantation is an option when deemed necessary for patients with CF who have end-stage liver disease. Indications include significant synthetic dysfunction, unresponsive or recurrent esophageal varices with recurrent upper GI bleeding, ascites, and encephalopathy. Patients need to be evaluated by a hepatologist. Ideal candidates are those with an FEV_1 of at least 50% of predicted. Colonization with a multidrug-resistant or panresistant strain of *Pseudomonas* is a relative contraindication to transplantation.

In patients in whom poor pulmonary function or drug-resistant pulmonary infection is an issue, double organ (liver and lung) transplantation may be considered. Despite concerns about worsening airway infection during transplant-associated immunosuppression, liver transplantation in patients with CF does not worsen their pulmonary status.[211]

Atelectasis

Atelectasis of a lung segment or lobe sometimes occurs in CF. Acute atelectasis is generally associated with few symptoms (Fig. 48-8A). If it is untreated, however, the end result of atelectasis is a severely bronchiectatic segment or lobe (Fig. 48-8B). Vigorous chest physiotherapy, in conjunction with antibiotics, is often successful in re-expanding the affected lung region. Bronchoscopy is occasionally helpful. As a rule, however, bronchoscopy is no more effective than chest physiotherapy and pulmonary pharmacotherapy. Resection of a persistently atelectatic or bronchiectatic lobe is undertaken only when the remaining areas of the lung are in relatively good condition, overall pulmonary function is good, and the evidence is convincing that the affected segment is responsible for intolerable symptoms (fever, cough, or sputum production).

Pneumothorax

Recurrent pneumothorax is common in CF, particularly in older patients (Fig. 48-8C). Tension pneumothorax occurs in up to 30% of patients with CF who develop pneumothorax. Tube thoracostomy is indicated when the pneumothorax occupies more than 10% of the area of the hemithorax seen on the posteroanterior chest radiograph. Because the frequency of recurrence of pneumothorax is high, attempts are often made at the time of the initial event to achieve chemical or surgical pleurodesis, although this is not recommended in existing guidelines.[212] Surgical pleurodesis is more effective at preventing recurrence of a pneumothorax and is no longer considered a contraindication to lung transplantation.

Hemoptysis

Expectoration of a small amount of blood-streaked sputum is a common occurrence in CF and is generally managed by intensifying home therapy for pulmonary infection. In contrast, hemoptysis (the expectoration of at least 30 to 60 mL of fresh blood) requires hospitalization, even with a chest radiograph that is virtually unchanged (Fig. 48-8D). The probable mechanism underlying most instances of hemoptysis in CF is the erosion of an area of localized infection into a bronchial vessel. Massive hemoptysis (blood loss of 240 mL) is uncommon in CF. However, it represents a potentially life-threatening situation. Bronchoscopy, and sometimes thoracic surgery, may be required to control the hemorrhage. Bronchial artery embolization has been used successfully in patients with CF and is now the treatment of choice when a physician experienced in the procedure is available.[213]

Infection with Unusual Organisms

CF produces central bronchiectasis, even though the disease initially is in the small bronchioles. Bronchiectatic airways are frequently colonized with unusual organisms, including *Aspergillus* and atypical mycobacteria. As is the case with pathogenic bacteria, eradication of these organisms from the airways is often not possible. The focus of therapy is directed toward verifying that the organisms are resulting in worsening of the disease and controlling the infection, rather than effecting a microbiologic cure.

Mycobacteria

The prevalence of infection with atypical mycobacteria in CF mandates surveillance for these organisms in sputum cultures at least

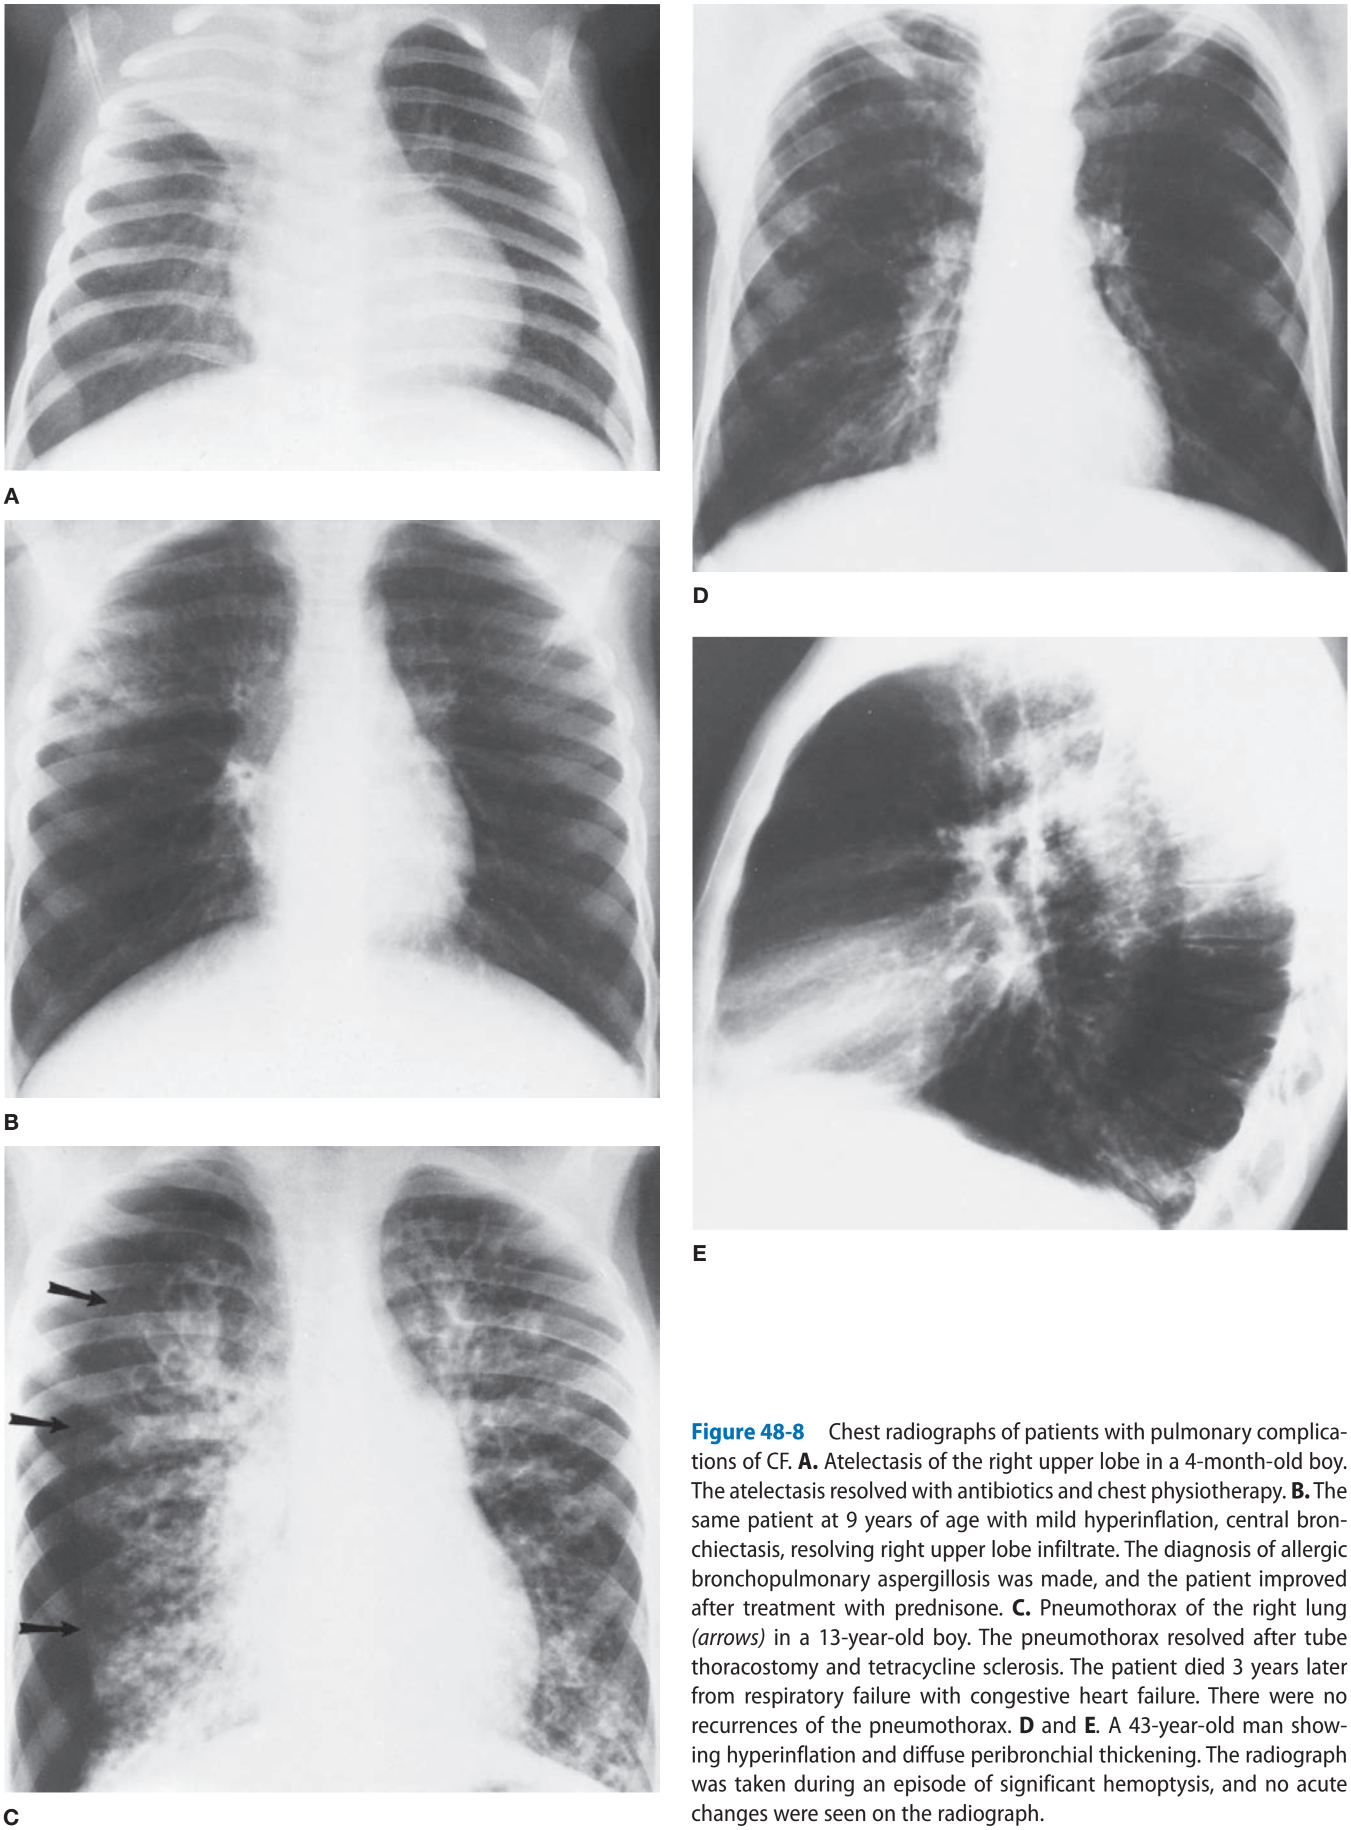

Figure 48-8 Chest radiographs of patients with pulmonary complications of CF. **A.** Atelectasis of the right upper lobe in a 4-month-old boy. The atelectasis resolved with antibiotics and chest physiotherapy. **B.** The same patient at 9 years of age with mild hyperinflation, central bronchiectasis, resolving right upper lobe infiltrate. The diagnosis of allergic bronchopulmonary aspergillosis was made, and the patient improved after treatment with prednisone. **C.** Pneumothorax of the right lung *(arrows)* in a 13-year-old boy. The pneumothorax resolved after tube thoracostomy and tetracycline sclerosis. The patient died 3 years later from respiratory failure with congestive heart failure. There were no recurrences of the pneumothorax. **D** and **E**. A 43-year-old man showing hyperinflation and diffuse peribronchial thickening. The radiograph was taken during an episode of significant hemoptysis, and no acute changes were seen on the radiograph.

annually.[214] When atypical mycobacteria are cultured, antimicrobial sensitivities should be obtained. A decision about therapy for isolation of atypical mycobacteria is based on the likelihood that the organism is contributing to airway infection and a decline in pulmonary function. Isolation of the same organism on several occasions, positive smears, presence of progressive chest radiographic changes, further decline in pulmonary status despite vigorous antipseudomonal (or antistaphylococcal) therapy, persistent night sweats, and fever are clinical clues that the atypical mycobacteria are contributing to disease. Demonstration of tissue infection with transbronchial lung biopsy is rarely recommended. A clinical database has been established by the CFF to track results of treatment for atypical mycobacterial infections in patients with CF. The current standard for therapy is treatment with several antimicrobials for synergy and to prevent development of resistance, and consensus guidelines have been published.[215]

Aspergillus

In an analogous fashion, molds, especially *Aspergillus*, are occasionally isolated from patients with CF. Approximately 5% to 15% of patients have allergic bronchopulmonary aspergillosis (ABPA) (see Chapter 46). The diagnosis of ABPA in CF is difficult because of overlapping symptoms between the two disorders. Diagnostic criteria for ABPA include (1) reversible airway obstruction, (2) proximal bronchiectasis, (3) history of pulmonary infiltrates, (4) skin test positivity to aspergillus antigens, (5) precipitating serum antibodies to *A. fumigatus*, (6) elevated total serum immunoglobulin E (IgE), (7) elevated specific serum IgE and serum immunoglobin G (IgG) to *Aspergillus*, and (8) peripheral eosinophilia. A negative skin test for *Aspergillus* effectively rules out the diagnosis of ABPA. During the active phase of ABPA, elevations in total IgE and eosinophil count are seen. Rises in *Aspergillus*-specific titers (IgE and IgG) are more specific for ABPA than are serum precipitins. ABPA in patients with CF is usually treated with corticosteroids and itraconazole; however, for patients who do not tolerate treatment with prednisone, omalizumab has been used.[216] The level of total IgE is used to follow the activity of the disease.

Gram-Negative Bacteria

In the late 1970s and early 1980s, the importance of *Burkholderia cepacia* (formerly *Pseudomonas cepacia*) was recognized. *B. cepacia* is a gram-negative, oxidase-positive rod that is uniformly resistant to polymyxin and, frequently, panresistant. Isolation of *B. cepacia* requires plating on special OFPBL (oxidative fermentative polymyxin B bacitracin lactose) or PC (*P. cepacia*) agar plates to retard growth of other gram-negative rods and enhance growth of *B. cepacia*. The plates must be maintained for a minimum of 4 days. *B. cepacia* colonization has been associated with septicemia, which is very rarely seen with *P. aeruginosa*.

The clinical course after acquisition of *B. cepacia* may be fulminant, with death occurring in a matter of months. However, most patients' disease follows a more benign course. Carefully controlled epidemiologic studies are needed to better define risk factors and to establish the true virulence of *B. cepacia*. Experimental evidence exists that at least one strain of *B. cepacia* may be transmitted in an epidemic fashion. The combination of a poor clinical course after acquisition of *B. cepacia* and the evidence supporting epidemic transmission has led to cohorting or isolation of patients with CF infected with *B. cepacia*, as recommended by the CFF and the Centers for Disease Control and Prevention (CDC).

In addition to being colonized with *Pseudomonas* and *Burkholderia* species, patients with CF may be colonized with other gram-negative, oxidase-positive organisms, such as *Stenotrophomonas maltophilia*, *Pseudomonas oryzihabitans*, and *Achromobacter xylosoxidans*. These are pathogenic organisms, similar in importance to *P. aeruginosa*. Antibiotic therapy should be directed toward these bacteria when they are isolated from the patient with CF who is experiencing an acute exacerbation.

The prolonged, suppressive use of antibiotics in CF has led to emergence of resistant organisms. A multiply resistant *Pseudomonas* is an organism that is resistant to all agents in at least two different classes of antibiotics. Resistance to oral fluoroquinolones occurs after about 3 weeks of therapy; if the agent is withheld, the organism occasionally becomes sensitive again. The existence of more refractory MDR strains has prompted investigation into the possibility of isolating and engineering a bacteriophage for use in treating these MDR strains of *Pseudomonas*.[217]

■ Respiratory Failure

As the pulmonary disease of CF progresses and the degree of hypoxemia increases, patients are at risk to develop pulmonary hypertension and cor pulmonale. An increase in hypoxemia often occurs during exacerbations of the pulmonary disease. During the acute episode, antibiotic treatment for the underlying pulmonary disorder is intensified and supplemental oxygen is added. Expectant monitoring and aggressive treatment of nocturnal hypoxemia (maintaining Sa_{O_2} ≥95%) prevent the onset of cor pulmonale. When respiratory failure develops in CF, that is, hypercarbia (Pa_{CO_2} at least 55 mm Hg) in addition to hypoxemia, management becomes extremely difficult.

Noninvasive mechanical ventilation using bilevel positive airway pressure has been used successfully in patients with end-stage CF awaiting lung transplant; it can improve oxygenation, reduce respiratory rate, and successfully transition to home nocturnal use.

Mechanical ventilation is generally instituted when an acute episode, such as viral pneumonia or status asthmaticus, leads to acute respiratory failure. This approach is indicated in the patient who has had good pulmonary function before the acute episode. Mechanical ventilation is less apt to be successful if the patient has previously experienced a bout of respiratory failure.

When respiratory failure marks the end of a chronic course of progressive pulmonary insufficiency despite adequate medical therapy, mechanical ventilation is usually unhelpful. None of the indications or contraindications for mechanical ventilation is absolute, however, and the clinical outcome depends, to a large extent, on the availability of a dedicated and skilled intensive care team experienced in caring for patients with CF.

■ Complications Related to Lung Transplantation

Lung transplantation has emerged as an option for patients with end-stage CF (see Chapter 106).[218–220] Despite initial concerns about immunosuppression in patients with suppurative lung disease, the outcome for those with CF who undergo lung transplantation is among the best reported for this procedure. Timing for lung transplantation has changed with the adoption of a lung allocation score (LAS), which takes into consideration parameters to predict 1-year survival, with a transplant versus without a transplant, and medical urgency. The impact of this organ allocation system is a dramatic decrease in the number of patients on the waiting list for transplantation and a significant shortening of wait times for transplantation.

One major complication post–lung transplantation for CF patients is the risk of infection due to resistant organisms. Colonization with *B. cepacia* complex, or rapidly growing mycobacteria such as *M. abscessus*, has been reported to negatively impact survival.[221] *Aspergillus* may cause invasive infections in the parenchyma or the anastomosis site. Other complications, not specific to CF patients, include acute and chronic graft rejection.

Acute graft rejection is associated with a humoral immune response to donor HLA antigens and complement activation.[222]

Importantly, acute graft rejection is a negative prognostic factor for chronic graft rejection.

Chronic allograft rejection is characterized by obliterative bronchiolitis following transplantation. Obliterative bronchiolitis is a progressive occlusion of the bronchiolar lumina by inflammatory cells and submucosal fibrosis. Transient improvement in airflow is seen following augmentation of immunosuppression. About 50% of transplant patients develop obliterative bronchiolitis after the second year following the procedure. The disease pursues a relentless downhill course, with a median survival of about 2 years following the initial diagnosis.

The poor prognosis associated with obliterative bronchiolitis has several important implications for patient selection and timing of referral for transplantation. First, the main reason for seeking lung transplant is to improve the quality of life, rather than to improve survival. Second, the timing of referral for lung transplantation needs to be calculated to optimize the candidate's fitness for transplant yet delay transplant until absolutely necessary considering the risk of developing obliterative bronchiolitis.

Results from clinical studies may aid with proper timing of referral for lung transplantation in CF. CF patients with severe airflow obstruction, as indicated by FEV_1 less than 30% of predicted, had a 50% 2-year mortality. Other important clinical parameters useful in determining the timing of transplantation are the presence of hypoxemia (PaO_2 under 55) and hypercarbia (Pa_{CO_2} above 50). Of interest, in both single and multivariate analyses, female sex is associated with an increased relative risk, suggesting that for female patients, referral for lung transplantation should be considered at an even earlier stage.

Because CF is a multisystem disorder, both management and proper selection of patients are more complicated than for other diseases managed with lung transplantation. Among the most difficult challenges presented by patients with CF before transplantation is the microbiology of their lower airways. As discussed previously, colonization with multidrug-resistant *B. cepacia*, specifically the genotype genomovar III, has been associated with a poor clinical outcome.

For poorly understood reasons, patients with CF metabolize drugs differently from those without CF, complicating the dosing of medications, including cyclosporine. The difficulties in achieving an optimal drug dose may be related to malabsorption or enhanced excretion of the drug.

Nutritional issues also complicate the posttransplantation management of patients with CF. About 50% of all patients with CF over 30 years of age are overtly diabetic, and administration of corticosteroids induces diabetes in another 10%. Maintenance of proper nutrition is important in CF, especially for rapid postoperative recovery. Finally, gastroesophageal reflux may negatively impact pulmonary outcomes following transplantation. Despite all the special challenges to successful lung transplantation posed by patients with CF, their actuarial survival is quite good. The 1-, 5-, and 10-year survival for adult transplant recipients in one large transplant center are 93%, 75%, and 57%, respectively.[223]

PSYCHOSOCIAL ISSUES

Psychosocial issues are important in the management of patients with CF. Special circumstances should be recognized for adults with the disorder. There is a high prevalence of depression and anxiety among patients with CF and their parents.[224] Anxiety and depression in parents adversely impact the ability to adhere to treatment for the child. In adults with CF, these issues impact their abilities in self-care.

General

Careful attention to the emotional, social, and financial well-being of the patient with CF and his or her family has considerable value in favorably influencing the course of the disease. At the time of diagnosis, it is important to strike an optimistic note while educating the patient about the illness and its management. As part of the early encounter with the patient, the importance of identifying and reinforcing the emotional and financial strengths of the family, as well as weaknesses that will need buttressing, should be recognized. Medical care for CF patients is costly, especially if hospital admissions are required. Many states have programs for children with disabilities that provide support for patients and families. Several states have also established special programs for adults with CF.

As the disease runs its course, counseling and feedback about disease progression are essential. As the patient and family go about setting educational, career, and family goals, they need guidance in realistic planning. It is vital that the physician develop and maintain a positive attitude. The patient who gives up hope is liable to undergo rapid deterioration. Conversely, even patients with severe pulmonary disease can continue to function well and be productive. At the stage when medical therapy is of no further avail, however, the patient and family require considerable emotional support to accept the inevitable. In recent years, many CF centers have allowed patients to die at home, rather than in the hospital. The family requires specific instructions about how to provide physical and emotional comfort for the patient in the home. Usually, home visits by some members of the CF team are required. Not all families have the strength or resources to care for the patient dying at home.

Special Considerations in Adult Patients

In 2020, the median life expectancy for patients with CF was about 46 years (CFF Patient Registry, 2019 Annual Data Report, Bethesda, MD). Managing a chronic illness becomes more complicated when patients must also begin to manage their independence and make life decisions regarding education, marriage, children, careers, insurance, and self-care.[225] Intense support for both patients and their families is required. Patients with a relatively mild clinical course of disease form healthy and satisfying relationships in a manner similar to their healthy, age-matched peers. With advanced disease, patients with CF have more difficulty in forming intimate relationships. Disturbances in body image, decreased mobility, and lack of opportunity to meet suitable partners are cited as reasons for the decreased ability to form intimate relationships in the severely affected young adult with CF.

The adult patient with CF faces unique problems with self-care. Families of patients with CF provide a tremendous amount of care that is expensive and time-consuming to replace for the independently living adult. When the disease flares, patients must "step up" their level of care at precisely the time when they are least able to do so. Judicious use of hospitalization and home care must be provided if the patient is to recover. The trend toward home management of a pulmonary exacerbation using intravenous antibiotics alone ignores the obvious contributions of nutrition, airway clearance, and rest toward resolution of the problem.

REPRODUCTIVE ISSUES

More than 98% of male patients with CF are sterile, secondary to bilateral absence of the vas deferens. Microsurgical epididymal sperm aspiration (MESA), coupled with in vitro fertilization, has been successful in producing pregnancies in a few carefully selected patients. Not all males with CF are sterile, however. In addition to counseling, these men should be offered semen analysis.

Pregnancy for women with CF is increasingly common, and several important issues remain unsolved. In 2004, 191 women with CF were pregnant (CFF Patient Registry, 2004 Annual Data Report, Bethesda, MD). This stands in marked contrast to the total of 13 pregnancies in 10 patients recorded from 1960 to 1966 (data from the 1994 CFF Data Registry).

Maternal clinical status before pregnancy is the most important prognostic factor of maternal outcome. In a study of 25 women with 38 pregnancies, no significant difference was seen between pre- and post-gravid gas exchange or nutritional status. A small but statistically significant decline in spirometry was noted. However, the decline was not outside the range of expected decline for the natural progression of the disease. More severely affected women suffered an irreversible decline in clinical status during pregnancy. Without an appropriately matched control group of nongravid women with CF, it was not possible to determine whether pregnancy per se was responsible for the decline or whether the decline is a reflection of the natural history of the disease. Comparison of matched groups of pregnant and non-pregnant CF women from a registry suggested that there was not a difference in the rate of decline between these groups. However the pregnant women received a greater number of therapies and more intense monitoring of their health.[226]

Recommendations about pregnancy for women who are either mildly affected or severely affected is straightforward. For the woman with moderately compromised pulmonary status (i.e., FVC_1 under 50%–60% of predicted), an overall assessment of the clinical situation is recommended, although no firm guidelines can be given. Increased incidence of fetal prematurity is noted in women with a pregravid FVC below 50% of predicted, lending additional weight against recommending pregnancy to women with moderate to severe airflow obstruction.

In any woman with CF who is contemplating pregnancy, thorough evaluation and treatment of nutritional deficiencies and pulmonary exacerbations are required. Frequent use of antibiotics is unavoidable, and the teratogenic risk of many antibiotics is unknown. Despite this theoretical risk, good maternal and fetal health depend on aggressive management of pulmonary exacerbations, including use of antibiotics. Management of the gravid patient with CF is best accomplished in a CF center that has a program in high-risk obstetrics.

A European consensus panel has published detailed guidelines for the management of pregnancy in women with CF.[227] Importantly, in the era of highly effective CFTR modulators, there are outstanding issues concerning pregnancy, lactation, and motherhood, including the impact of the modulators on fertility, exposure via lactation, and effect on offspring.[228]

For men with CF who opt for microepididymal sperm aspiration (MESA) and for women with CF who are contemplating pregnancy, all offspring are obligate heterozygotes for CF. These offspring need to be counseled that their risk of having a child with CF is about 1 in 50 if the genotype of the spouse is not known. Although genetic testing of children from affected parents is not recommended, they should receive genetic counseling on reaching adolescence.

Parents with CF also need to consider the ethical issues of a premature parental death and its effect on the family. If the spouse of a CF individual is a known carrier of a CF mutation, the availability of in vitro fertilization with preimplantation genetic testing provides a method to avoid having a child who is affected with CF. Discovery of the CF gene in 1989 led to the hope that prenatal diagnosis might eventually decrease the incidence of the disease. There is a suggestion that this may, in fact, be occurring.[229]

FUTURE DIRECTIONS

The timeline of progress in CF research and care from its initial description in the 1930s through 2017 was summarized by Ramsey and Welsh.[230] The most dramatic improvement in the care of CF patients occurred with the approval of Trikafta in the waning months of 2019. Patients who have received this triple therapy often describe it as a “game changer.” As of June 2021, the drug is available to CF patients 6 years of age and older who have either at least one copy of delF508 or one copy of other approved mutations.

To further enhance survival and quality of life in CF beyond the initial robust improvements that many CF patients have experienced from Trikafta, and to include all CF patients in treatment with highly effective CFTR modulators, physicians must look to insights gained from basic research. A tremendous amount has already been accomplished, warranting a realistic expectation that additional breakthroughs will soon occur in the treatment of the disorder. Some additional areas for investigation include harnessing new information about the CF microbiome to better treat resistant infections, and new modes of therapy to tackle unopposed protease in the airway and the associated, unrelenting inflammation to prevent progression of CF lung disease.

Progress toward the CFF’s goal of leaving no CF patient behind will require a multidisciplinary approach. Management of the lung disease in CF will probably be based on combined methods. However, the momentum gained from improved understanding of the molecular details of CFTR structure and the ability to improve its function makes it more likely that specific therapy will eventually result in better outcomes for all patients with CF.

New approaches to correct premature termination codon mutations or promote mRNA read-through and prolong mRNA half-life are being developed. Genetic engineering is also being applied to new therapies to correct any CFTR.[231–233] The envelope was pushed even further by the demonstration that administration of a CFTR modulator to pregnant CF ferrets resulted in male pups with normally developed vas deferens.[26] This suggests that early or in utero treatment of individuals who have a CF genotype may prevent or inhibit the development of some, or possibly all, of the clinical hallmarks of CF. While this is certainly speculative now, recent progress in research provides a solid foundation for optimism.

CHAPTER 49

Bronchiolitis

Gary R. Epler

INTRODUCTION

Diseases of the bronchioles occur throughout the bronchiolar structures, from bronchiolar airways to alveolar ducts and alveoli (Table 49-1). Acute and chronic bronchiolitis are seen from near the bronchi, all the way to the respiratory bronchioles; constrictive bronchiolitis is seen in the mid-bronchioles, while diffuse panbronchiolitis occurs from the distal bronchioles to the respiratory bronchioles, and smoker's bronchiolitis involves the respiratory bronchioles. Bronchiolitis obliterans organizing pneumonia (BOOP) includes both the terminal bronchioles and alveoli and is discussed more fully in Chapter 55.

This chapter includes a discussion of the pathologic, clinical, and radiographic findings, as well as treatment of the bronchiolar airway disorders.

BRONCHIOLAR ANATOMY

Bronchioles are noncartilagenous small airways that are usually 1 mm or less in diameter; they have been called the bridge between the bronchi and alveoli.[1] The bronchioles have cartilage and mucus glands that are commonly found in the bronchi, but bronchioles also contain ciliated epithelium, smooth muscle, and bronchiolar exocrine cells.[2] Neuroendocrine cells are common in the proximal bronchioles.

More distal in the airways are approximately 30,000 terminal bronchioles that have an average diameter of about 0.6 mm. These bronchioles have circular smooth muscles in their walls; the surface cilia gradually disappear distally. Terminal bronchioles branch into 224,000 respiratory bronchioles that differ from the bronchioles: respiratory bronchioles have two to three alveolar structures in the walls containing columnar cells with cuboidal type II cells and squamous type I cells. These structures terminate in 13.8 million alveolar ducts and 300 million alveoli.

THE CLINICAL SPECTRUM OF THE BRONCHIOLAR DISEASES

The wide variety of bronchiolar diseases that may be seen in clinical practice are discussed below.

TABLE 49-1 Clinical Classification of the Bronchiolar Diseases

Airway diseases
• Acute and chronic bronchiolitis
• Respiratory bronchiolitis
• Follicular bronchiolitis
• Diffuse panbronchiolitis
• Bronchiolitis obliterans
Interstitial diseases
• Respiratory bronchiolitis–interstitial lung disease (RB-ILD)
• Bronchiolitis obliterans organizing pneumonia (BOOP)

■ Acute and Chronic Cellular Bronchiolitis

Acute and chronic cellular bronchiolitis is characterized pathologically as acute or chronic inflammation of the bronchioles without a fibrotic component.[3,4] The inflammation may be submucosal, mural, or peribronchiolar. Although common in infants and children, in the adult, bronchiolitis is rare and may be caused by respiratory syncytial virus, adenovirus, influenza, *Mycoplasma pneumoniae*, *Streptococcus pneumoniae*, and *Haemophilus influenzae* as well as acute toxic inhalational injury. Symptoms include a flu-like illness with fever and persistent nonproductive cough of several weeks' duration. There is generally no wheezing and no airflow obstruction. The chest x-ray is often normal, although the chest CT scan may show tree-in-bud opacities, ill-defined nodules, and ground-glass opacities.[4] The illness usually subsides over time. Cough suppressants may be utilized. Sometimes, a brief course of corticosteroid therapy is given for a severe, relentless cough. If symptoms are not responsive to corticosteroid therapy or if symptoms worsen, the illness may be fibrotic constrictive bronchiolitis—a disorder with a different clinical course and prognosis.

■ Respiratory Bronchiolitis

Respiratory bronchiolitis is sometimes called smoker's bronchiolitis, as cigarette smoking is almost always the cause of this disorder.[3,5] The characteristic histologic feature is the accumulation of tan-brown macrophages in the lumens of respiratory bronchioles and adjacent alveoli, often seen as an incidental finding in cigarette smokers. There are usually no clinical symptoms associated with this type of respiratory bronchiolitis. Treatment is smoking cessation.

In some situations, respiratory bronchiolitis may extend into the interstitium and is referred to as respiratory bronchiolitis–interstitial lung disease (RB-ILD).[4–6] Affected individuals have shortness of breath, bilateral crackles, reticulonodular opacities on chest radiography, decreased vital capacity, and decreased diffusing capacity. Treatment is smoking cessation, but often a course of corticosteroid therapy is needed for resolution.

■ Follicular Bronchiolitis

Follicular bronchiolitis is characterized by hyperplastic lymphoid aggregates forming 1- to 2-mm peribronchiolar nodules.[3,4,7] Follicular bronchiolitis is often limited to a pathologic description with no clinical counterpart. There may be an underlying systemic disease such as immunodeficiency syndromes or infections such as *Legionella* or *Pneumocystis*. In some patients, there may be cough and small linear radiographic opacities or hyperinflated lungs, and very rarely, advanced disease.[7]

■ Diffuse Panbronchiolitis

Diffuse panbronchiolitis is a chronic diffuse bronchiolar inflammatory disease that is strongly associated with human leukocyte antigen (HLA) alleles, especially HLA-A and HLA-B.[8] It is characterized by chronic inflammation and lymphofollicles of the respiratory bronchioles and adjacent centrilobular regions, with infiltration of histiocytosis, plasma cells, and lymphocytes.[9] There is an interstitial accumulation of foam cells in the walls of respiratory bronchioles and adjacent alveolar ducts and alveoli (Fig. 49-1). The disorder is largely restricted to the Asian countries but has been reported throughout the world.

Symptoms include chronic cough, sputum production, and shortness of breath, and almost all individuals have chronic paranasal sinusitis. Rhonchi and crackles are common. Radiographic findings show hyperinflation and diffuse small nodular opacities bilaterally. Pulmonary function testing shows airflow obstruction with decreased

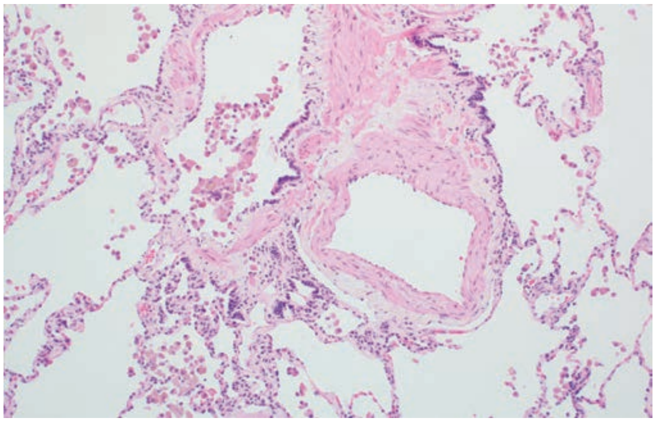

Figure 49-1 Respiratory bronchiolitis is appreciated as clusters of lightly pigmented macrophages within the lumen of a terminal airway and peribronchiolar airspaces (hematoxylin-eosin, original magnification ×100). *(Reproduced with permission from Konopka KE, Myers JL. A Review of Smoking-Related Interstitial Fibrosis, Respiratory Bronchiolitis, and Desquamative Interstitial Pneumonia: Overlapping Histology and Confusing Terminology. Arch Pathol Lab Med. 2018;142(10):1177–1181.)*

forced expired volume in 1 s (FEV_1) and FEV_1 to forced vital capacity (FEV_1/FVC) ratio. Hypercapnia and cor pulmonale occur late. There is often an associated increase in the cold-hemagglutinin titer.

The disorder is progressive. In the past, diffuse panbronchiolitis was a fatal disease with a 10-year survival of less than 20% in patients with *Pseudomonas aeruginosa* infection. However, the use of macrolides has resulted in a dramatic improvement in survival.[10]

Bronchiolitis Obliterans

Bronchiolitis obliterans can be severely disabling and deadly. Traditionally, bronchiolitis obliterans has been used as a clinical term to describe irreversible fibrosis of the bronchiolar airway that is idiopathic or occurs after accidental toxic fume inhalation or a viral pneumonia. However, pathologists may see two distinctive lesions that, in turn, have a different clinical course and response to treatment.

Histologically, the two lesions are *proliferative bronchiolitis* and *constrictive bronchiolitis* (Table 49-2). Depending on severity, obliteration of the bronchioles (the *obliterans* term) may or may not occur with these lesions. The histologic distinction between these two lesions is that constrictive bronchiolitis arises in a concentric fashion outside the bronchiole walls as a fibrotic lesion, while proliferative bronchiolitis arises from within the bronchiole walls as an inflammatory lesion.

The term *bronchiolitis obliterans* is used in this chapter, as it has been used by clinicians for more than 100 years and almost always reflects the fibrosing, constrictive, pathologic lesion.[11] The proliferative lesion is often self-limiting and less severe, or responds to corticosteroid therapy with complete resolution; it usually does not result in the clinical label of bronchiolitis obliterans.

Proliferative bronchiolitis is an inflammatory bronchiolitis characterized by intraluminal polypoid connective tissue masses of myxoid fibroblastic tissue, which resembles granulation tissue that arises from within the bronchioles.[1] Central clusters of mononuclear inflammatory cells may be found in these polypoid masses. This type of bronchiolitis includes organized polypoid granulation inflammatory tissue in the distal bronchiole airways, respiratory bronchioles, alveolar ducts, and alveoli in the form of BOOP.[12] Additional, distinctive histologic findings with proliferative bronchiolitis associated with BOOP include no disruption in the lung architecture, interstitial fibrosis, absence of traction bronchiectasis, or histologic honeycombing (Fig. 49-2).

Constrictive bronchiolitis is a fibrotic, concentric bronchiolitis lesion with or without complete obliteration (Fig. 49-3). This lesion is usually seen in the middle to distal portions of bronchioles and does not extend into the respiratory bronchioles or alveoli. The lesion is characterized by a peribronchiolar fibrotic process that surrounds, rather than fills, the lumen, resulting in extrinsic compression and obliteration of the airway.[3,4] There is mural thickening by submucosal collagenous fibrosis, with progressive concentric narrowing associated with luminal distortion, mucus stasis, and chronic inflammation.

Constrictive bronchiolitis was called “fibrosing bronchiolitis” in the German pathology literature.[13] The lesion preferentially involves membranous bronchioles and is characterized by fibrosis of the stroma and narrowing the lumen in a concentric fashion. The muscle layer may be hypertrophic in early lesions, atrophic in late stages, and replaced by fibrotic tissue at the end stage. Visscher and Myers noted that constrictive bronchiolitis is often patchy and focal, making the diagnosis difficult from a transbronchial biopsy; advanced cases may be especially inconspicuous because of lack of active inflammation and disappearance of bronchioles.[14]

There are several causes of bronchiolitis obliterans and associated systemic disorders (Table 49-3).

TABLE 49-2 Pathologic Findings of Bronchiolitis Obliterans

Constrictive bronchiolitis

- Concentric fibrotic lesion of the mid to distal bronchioles
- Surrounds the lumen causing extrinsic narrowing and obliteration
- Distortion of the lumen and mucostasis
- Muscle layer hypertrophic early, atrophic late, and replaced by fibrotic tissue in end stage
- May be patchy and focal
- Late stage includes traction bronchiectasis and bronchiolectasis

Proliferative bronchiolitis

- Intraluminal polypoid myxoid fibroblastic tissue arising with the bronchiole wall
- May be organized polypoid granulation tissue from the bronchioles to the respiratory bronchioles and including the alveoli
- No disruption of the lung architecture
- No traction bronchiectasis

Idiopathic Bronchiolitis Obliterans

Idiopathic bronchiolitis obliterans occurs among individuals who have no obvious inciting agent or associated systemic disorder, and who have airflow obstruction and constrictive bronchiolitis histologically. This disorder continues to be exceedingly rare. Symptoms begin with a nonproductive cough, and shortness of breath develops later. Physical examination shows no wheezing but may demonstrate an unusual finding of early inspiratory crackles. The crackles occur early because of the scarring around the mid-bronchiole airways, causing snapping closure of the airways and resultant crackling sound.

Pulmonary function studies show irreversible decrease in the FEV_1 and FEV_1/FVC, with no improvement after bronchodilator inhalation. The diffusing capacity is highly variable, from increased, to normal, to markedly decreased.

The chest roentgenogram is often normal or shows hyperinflation. High-resolution chest CT scans during inspiration and expiration can be helpful for establishing a diagnosis. For example, a normal

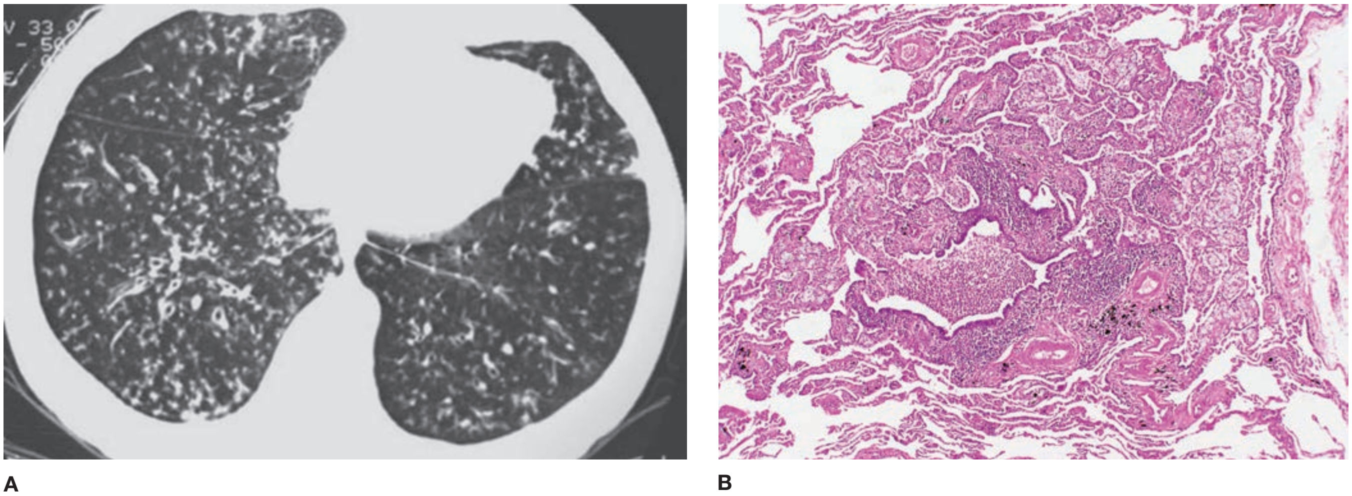

Figure 49-2 Diffuse panbronchiolitis. **A.** The chest CT scan shows bilateral centrilobular nodules with branching showing "tree-in-bud" pattern. **B.** The pathology micrograph shows chronic inflammation of the respiratory bronchioles, with interstitial accumulation of foam cells in the walls of the respiratory bronchioles, adjacent alveolar ducts, and alveoli. *(Reproduced with permission from Dr. Kenneth W. Tsang, Queen Mary Hospital, Hong Kong, China and Dr. Thomas V. Colby, Lung Pathology, Mayo Clinic Scottsdale.)*

chest CT scan may be seen in the inspiratory phase of the study, but the expiratory study will show lobular air trapping. These expiratory images show low-attenuation areas in the secondary pulmonary lobules, resulting in a typical mosaic pattern with scattered areas of low attenuation. Additional CT findings include constriction of the pulmonary vessels within the low-attenuation areas, expiratory air trapping, bronchial dilation, and, sometimes, tree-in-bud configuration with centrilobular nodules and branching linear densities.[4]

Treatment consists of corticosteroids at a high initial dose followed by lower-dose therapy for up to 1 year in patients who respond. For those who do not respond by 3 months, corticosteroids are discontinued and employed for life-threatening exacerbations. Immunosuppression treatment and lung transplantation are considered for individuals with life-threatening and severe disease.

Patients who survive the initial episode may stabilize for several years or progress to end-stage airflow disease and cor pulmonale. Myong et al.[15] described three women, aged 41 to 54, who developed cough and progressive shortness of breath over the course of 6 months to 10 years; lung pathology showed constrictive bronchiolitis with bronchiolar airway obliteration. The thin-section CT scans showed low-attenuation changes of the mosaic pattern. None responded to corticosteroid treatment.

Toxic Fume Bronchiolitis Obliterans

Toxic fume bronchiolitis obliterans is a three-phase response disease. The exposure usually occurs from an accidental explosion resulting in nose, throat, and eye irritation with no major respiratory symptoms. Phase one is an asymptomatic latency period of 6 to 12 h after exposure. Phase two begins suddenly with acute-onset respiratory failure with a white-out of the lung. If there is recovery from this acute phase, there is another asymptomatic latency period of 7 to 10 days. Phase three then occurs as constrictive bronchiolitis with irreversible airflow obstruction, progressive shortness of breath, and chronic respiratory failure.

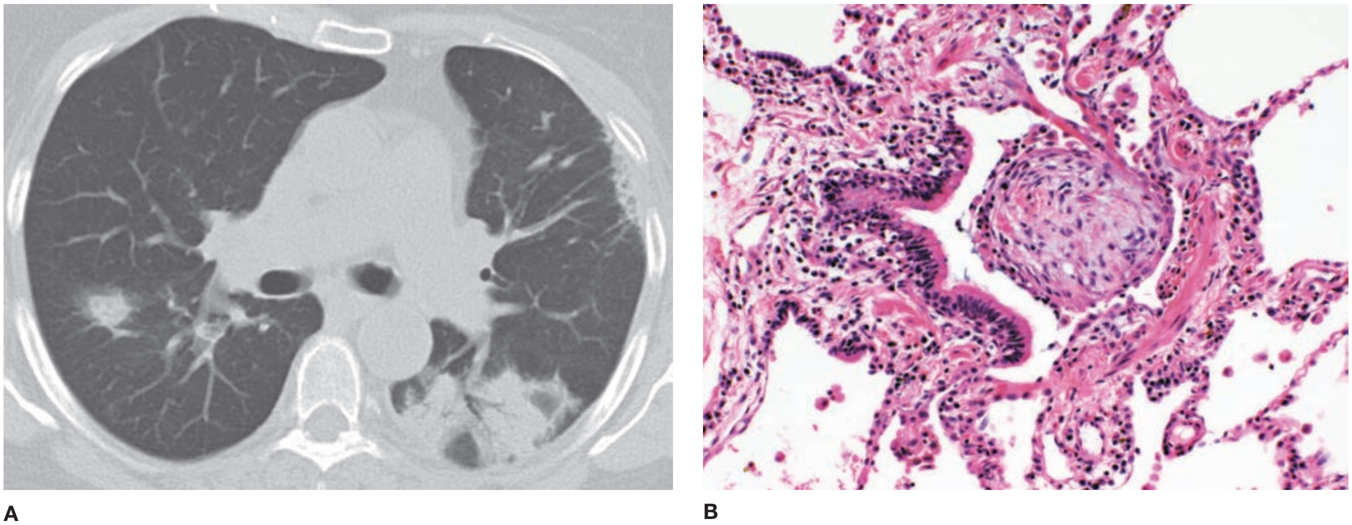

Figure 49-3 Bronchiolitis obliterans organizing pneumonia. **A.** The chest CT scan shows bilateral patchy ground-glass opacities, air bronchograms, and peripheral-based triangular infiltrates. **B.** The pathology micrograph shows organized polypoid granulation tissue filling the distal bronchiole and extending into the alveoli. *(Reproduced with permission from Dr. Ritu R. Gill, Chest Radiology, Brigham and Women's Hospital, Boston and Dr. Thomas V. Colby, Lung Pathology, Mayo Clinic Scottsdale.)*

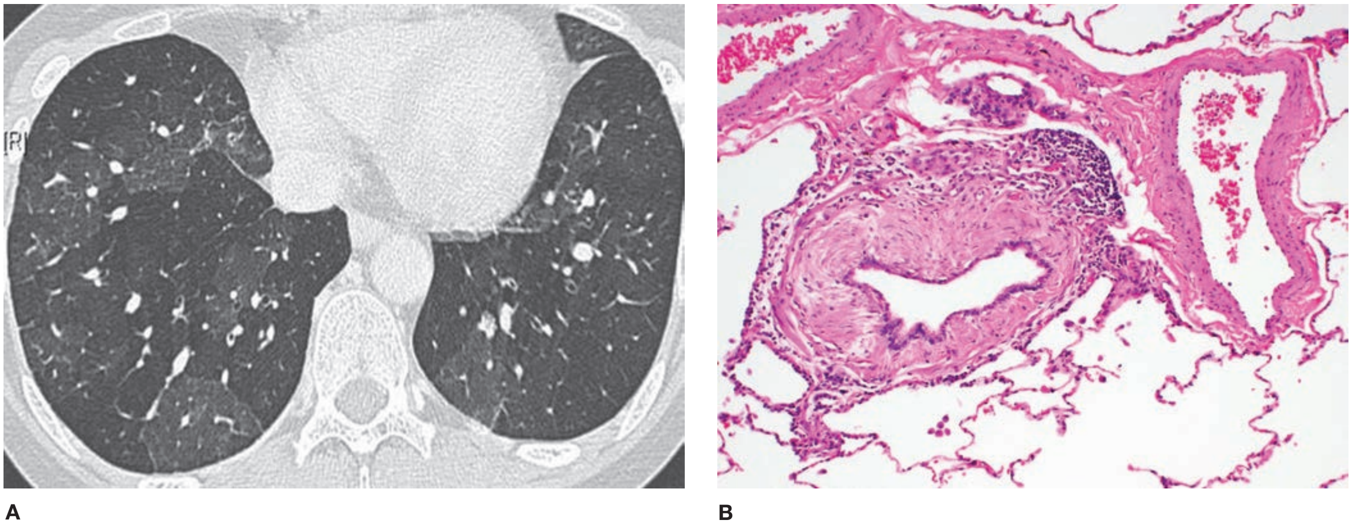

Figure 49-4 Constrictive bronchiolitis. **A.** The expiratory chest CT scan shows the mosaic pattern of air trapping seen from obliterated bronchioles. **B.** The pathology micrograph shows extrinsic fibrosis of the bronchiolar wall in a concentric manner constricting and obliterating the bronchiolar lumen. *(Reproduced with permission from Dr. Ritu R. Gill, Chest Radiology, Brigham and Women's Hospital, Boston and Dr. Thomas V. Colby, Lung Pathology, Mayo Clinic Scottsdale.)*

This disorder occurs after exposures to sulfur dioxide fumes,[16] nitric acid fumes, and nitrogen dioxide in freshly filled corn silos. Unusual accidental exposures to toxic fumes may cause the syndrome such as in a metal-cutting worker.[17] For example, two workers in a lithium battery factory were accidentally exposed to thionyl chloride, and one of them developed findings consistent with bronchiolitis obliterans.[18] This acidic compound is used in the manufacturing process and produces sulfur dioxide and hydrochloric acid fumes when in contact with water.

Smoke inhalation bronchiolitis obliterans was described in a 23-year-old man who was in a fire while sleeping in his newly constructed house.[19] He was unconscious when rescued. There was cough and mild dyspnea after recovery. He returned 3 years later because of persistent dyspnea. He had finger clubbing, an FEV_1 of 0.90 L, and an FEV_1/FVC of 34%. The burning synthetic structural materials used to build his house produced gases containing acrolein, formaldehyde, acetaldehyde, nitrogen dioxide, and sulfur dioxide.

Diacetyl appears to be a common exposure among artificial butter flavoring workers who developed constrictive bronchiolitis.[20] The use of e-cigarettes may cause severe bronchiolitis.[21]

TABLE 49-3 Clinical Classification of Bronchiolitis Obliterans

Idiopathic
Toxic fumes
Post–respiratory infections
Connective tissue disorders
Drug-related
Organ transplantation • Bone marrow and stem cell • Lung
Aspiration
Neuroendocrine hyperplasia with carcinoid
Sauropus androgynous
Miscellaneous system diseases • Stevens–Johnson syndrome • Paraneoplastic pemphigus • Primary biliary cirrhosis • Swyer–James syndrome • Ataxia telangiectasia • Inflammatory bowel disease

Post–Respiratory Infection Bronchiolitis Obliterans

Post–respiratory infection bronchiolitis obliterans may occur after adenovirus pneumonia, influenza or parainfluenza pneumonia, or *Mycoplasma* pneumonia.[22] Cough develops several days after the initial infection. Chest radiographs may show diffuse reticulonodular opacities early in the course, but they are normal or show hyperinflation later in the course of the illness. Expiratory, high-resolution chest CT scans show a low-attenuation mosaic pattern. Histology shows constrictive bronchiolitis with extensive scarring that obliterates many of the bronchioles, corresponding clinically with severe airflow obstruction. At this stage, the lesion is not responsive to corticosteroids, and lung transplantation is a treatment option. Covid-19 infection may cause BOOP but has not yet been found to be a cause of constrictive bronchiolitis obliterans.[12,23]

Connective Tissue Disease–Associated Bronchiolitis Obliterans

Connective tissue disease–associated bronchiolitis obliterans occurs most commonly in rheumatoid arthritis and has been reported in scleroderma, lupus erythematosus, and Sjögren syndrome.[24–26] Shortness of breath is the most common presenting symptom. Pulmonary function shows irreversible airflow obstruction, and chest imaging shows mosaic attenuation pattern with air trapping on expiratory views.

Rheumatoid arthritis–related constrictive bronchiolitis often has a poor prognosis, tends not to respond to therapy, and may require lung transplantation.[25] Among 11 patients with Sjögren syndrome, all had shortness of breath, chest imaging was normal in two-thirds, and hyperinflation was seen in the remaining one-third. Most patients did not respond to immunosuppressive therapy.[26] There has been a report of constrictive bronchiolitis occurring in ankylosing spondylitis in a patient who had a poor response to therapy.[27]

Paraneoplastic pemphigus has been reported as a cause of bronchiolitis obliterans that may have a fatal outcome.[28,29]

Drug-Related Bronchiolitis Obliterans

Drug-related bronchiolitis obliterans is rare and has been reported with use of penicillamine and gold in the treatment of rheumatoid arthritis. Afatinib may be a cause, with one case report describing severe shortness of breath, severe airways obstruction, mosaic pattern on chest CT, and at autopsy, lung findings of concentric fibrotic bronchiolitis with bronchiolitis obliterans.[30] There has been a report of a 54-year-old woman who developed constrictive bronchiolitis from imatinib.[31] Pembrolizumab has been reported as a cause of new-onset, severe, nonreversible airflow obstruction, chest imaging with mosaic attenuation, and minimal response to therapy.[32]

Bone Marrow Transplantation Bronchiolitis Obliterans

Bronchiolitis obliterans occurs between 6 and 12 months after transplantation and occurs in up to 10% of allogeneic bone marrow recipients. It occurs in patients with chronic graft-versus-host disease and therefore is rarely seen after autologous bone marrow transplantation. The chest CT scans show mosaic pattern with air trapping. Because this air trapping is better seen on expiratory images, for some younger patients, inspiratory studies can be eliminated resulting in less ionizing radiation.[33] The pathologic lesion is concentric bronchiolar fibrosis typical of constrictive bronchiolitis. There is generally a poor response to corticosteroid therapy with a mortality rate of more than 50%.

Stem Cell Transplant Bronchiolitis Obliterans

Stem cell transplant bronchiolitis obliterans has replaced bone marrow transplantation–associated bronchiolitis obliterans, as allogeneic hematopoietic stem cell transplantation is widespread (see Chapter 94). The diagnosis of bronchiolitis obliterans is based on the National Institutes of Health (NIH) diagnostic criteria where all four must be met, including an FEV_1/FVC ratio of less than 70% or the 5th percentile of predicted; FEV_1 less than 75% of predicted with 10% or more decline over less than 2 years; absence of respiratory infection; and expiratory chest CT showing air trapping or residual volume more than 120% of predicted.[34]

The prevalence of bronchiolitis obliterans ranges from 2% to 7% with a poor 5-year survival rate of 10%. Among 27 patients with stem cell bronchiolitis obliterans, all but 1 developed graft-versus-host disease, time to diagnosis was 18 months, and the mean FEV_1 was 44%.[35] Respiratory infections were a risk factor. The chest CT findings showed air trapping in 15 and bronchiectasis in 10.

Biopsies performed early show bronchiolitis, fibrous obliteration of the respiratory bronchioles, and inflammatory cell infiltrates; later lesions include constrictive bronchiolitis with circumferential fibrosis, and the mechanism is based on chronic rejection. Treatment includes high-dose systemic corticosteroids and immunosuppression.[36] Extracorporeal photodynamic therapy may be used successfully if used early.[37] Ruxolitinib[38] and nintedanib[39] have been used for treatment.

Lung Transplant Bronchiolitis Obliterans

Lung transplant bronchiolitis obliterans has continued to plague thoracic surgeons and patients, with minimal improvements over time in frequency or mortality (see Chapter 106).

The short-term survival within 1 year is more than 80%, while chronic lung allograft dysfunction (CLAD) continues to be the most common cause of poor long-term survival, as half of recipients develop CLAD within 5 years, and the survival at 5 years remains 50% to 70%.[40] Initially, CLAD was recognized as bronchiolitis obliterans syndrome (BOS) that was constrictive bronchiolitis with obliteration pathologically. Later, the concept of restrictive allograft syndrome (RAS) was designated, occurring in 25% to 33% of CLAD. RAS is characterized by an irreversible decline in FEV_1 and total lung capacity, upper lobe predominance radiographically, diffuse alveolar damage and fibrosis as well as pleuroparenchymal fibrosis, and a poor prognosis.[41]

Risk factors for bronchiolitis obliterans include acute cellular rejection and lymphocytic bronchiolitis as well as primary graft dysfunction, gastroesophageal reflux disease, and respiratory infections.[41] Treatment consists of fluticasone inhaler, azithromycin and montelukast (FAM), extracorporeal photopheresis, and pulmonary rehabilitation. Loading imatinib inside targeted nanoparticles is being studied.[42]

Aspiration Bronchiolitis Obliterans

Aspiration bronchiolitis obliterans was first reported in 1908 in a 2.5-year-old child who aspirated a prune pit that eventually caused respiratory failure and death.[43] Obliterative bronchiolitis has been reported in a 61-year-old man who aspirated an iron pill.[44] Gastroesophageal reflux can be a cause of bronchiolitis obliterans.[45,46]

Neuroendocrine Hyperplasia–Related Bronchiolitis Obliterans

Neuroendocrine hyperplasia–related bronchiolitis obliterans was described in a series of 44 patients.[47] Most of these patients were females with a median age of 65 years. Cough and shortness of breath were common symptoms. Pulmonary function showed airflow obstruction in 51% and restrictive pattern in 11%. The chest CT showed diffuse nodules in 95% and mosaic attenuation in 77%. Among these patients, 34 had carcinoid tumorlets and 16 had carcinoid tumors. For treatment, 25% were observed without therapy, 41% received inhaled corticosteroid, and 32% received systemic steroid or immunosuppressive agents. Follow-up showed 50% remained stable, 33% worsened, and 17% improved.

Sauropus androgynus Bronchiolitis Obliterans

Sauropus androgynus bronchiolitis obliterans has been reported among women who consume this leafy vegetable.[48] It is cultivated in India, Malaysia, Indonesia, China, and Vietnam. The leaves are boiled and blended with pineapples or guavas to make a mixed vegetable-fruit juice, which is consumed for its alleged effects of body weight reduction and blood pressure control. The leaves contain the alkaloid papaverine. Among 178 patients in Taiwan, the obstructive ventilatory defect was irreversible and resulted in progressive deterioration in some patients, resulting in lung transplantation.[49]

Miscellaneous Systemic Disorders Associated with Bronchiolitis Obliterans

Stevens–Johnson–related bronchiolitis obliterans continues to be reported from various types of antibiotics including phenytoin[50] and cefuroxime,[51] resulting in severe airflow obstruction. Paraneoplastic pemphigus has been reported as a cause of bronchiolitis obliterans.[52,53] Other disorders as a cause of bronchiolitis obliterans include primary biliary cirrhosis, Swyer–James syndrome, ataxia-telangiectasia, and inflammatory bowel disease.

SUMMARY

In summary, the bronchiolar airway diseases include acute and chronic bronchiolitis, follicular bronchiolitis, diffuse panbronchiolitis, and bronchiolitis obliterans. Acute bronchiolitis is usually transient, whereas diffuse panbronchiolitis responds to macrolide therapy. Post–lung transplantation bronchiolitis obliterans continues to be a major problem, with minimal change in frequency or response to treatment.

CHAPTER 50

Bullous Lung Disease

Fernando J. Martinez

DEFINITIONS

A *bulla* is an air-containing space within the lung parenchyma that arises from destruction, dilation, and confluence of airspaces distal to terminal bronchioles and is larger than 1 cm in diameter (Fig. 50-1).[1] Its walls are composed of attenuated and compressed parenchyma. Bullae occur in various clinical contexts: (1) with emphysema ("bullous emphysema"); (2) with pulmonary fibrosis, as in the late stages of sarcoidosis, complicated pneumoconiosis, or COVID-19;[2] (3) in "vanishing lung," in which the parenchyma is rapidly replaced by multiple bullae; and (4) in lungs that are otherwise normal ("bullous lung disease") and, therefore, likely secondary to a mechanism different from that of bullae occurring in conjunction with emphysema (Table 50-1).[3,4] Distinctions are drawn between bullae, blebs, and cysts (Table 50-2).[3] A *bleb* is an accumulation of air between the two layers of the visceral pleura that arises when the thin covering of the bleb ruptures and permits entry of air (Fig. 50-1). *Cysts* are epithelial-lined cavities that may resemble bullae on radiographs.[4] Many fall into the category of developmental anomalies and include mixtures of mesenchymal and epithelial components that are normally present in the lung. The pathologic nature of these cystic lesions is reflected in their names: "cystic adenomatoid malformations," "peripheral bronchogenic cysts," "congenital polycystic disease," and "atypical bronchopulmonary sequestration."[1]

The term *bullous disease* is reserved for multiple bullae in lungs that are otherwise normal.[3] This entity is different in etiology and pathogenesis from that in which bullae occur in conjunction with underlying chronic obstructive pulmonary disease (COPD). Confusion occasionally arises between the two entities because some pathologists regard bullous disease as a subset of panacinar emphysema.[1] However, this view is not useful as (1) panacinar emphysema tends to occur in the lower lobes, whereas bullous disease favors the upper lobes; (2) the natural history of the two disorders is quite different; and (3) panacinar emphysema has certain distinctive features not shared by bullous disease. Bullae may occur not only as part of obstructive lung disease, but also as a complication of fibrotic lung disease (Table 50-1).

ETIOLOGY

Bullae may originate in a variety of clinical and pathogenetic settings: (1) with emphysema of distal acini; (2) in the setting of cigarette and marijuana smoking; (3) in conjunction with scar tissue formation, which "traps" areas of normal lung, enlarges airspaces by traction on surrounding intact alveoli, or produces retraction or shrinkage of intact walls of adherent alveoli; (4) in the setting of intravenous drug abuse; (5) as a result of chronic inflammation and destructive changes in terminal and first-order respiratory bronchioles, resulting in airspace distention from delayed emptying; and (6) with α_1-antitrypsin deficiency.[3,5–7]

CLASSIFICATION

Bullae are classified anatomically into three main types (Fig. 50-1B).[1,3] Type I bullae are characterized by a narrow neck that connects the bullae with the pulmonary parenchyma. This type of bulla may be caused by overinflation of a volume of flawed lung tissue. The walls of type I bullae are thin, and their interiors are empty. Type I bullae are usually found at the lung apices and along the edges of the lingula and middle lobes. They often occur in association with paraseptal emphysema. Scanning electron microscopy has demonstrated that the thin neck is a consistent feature and that

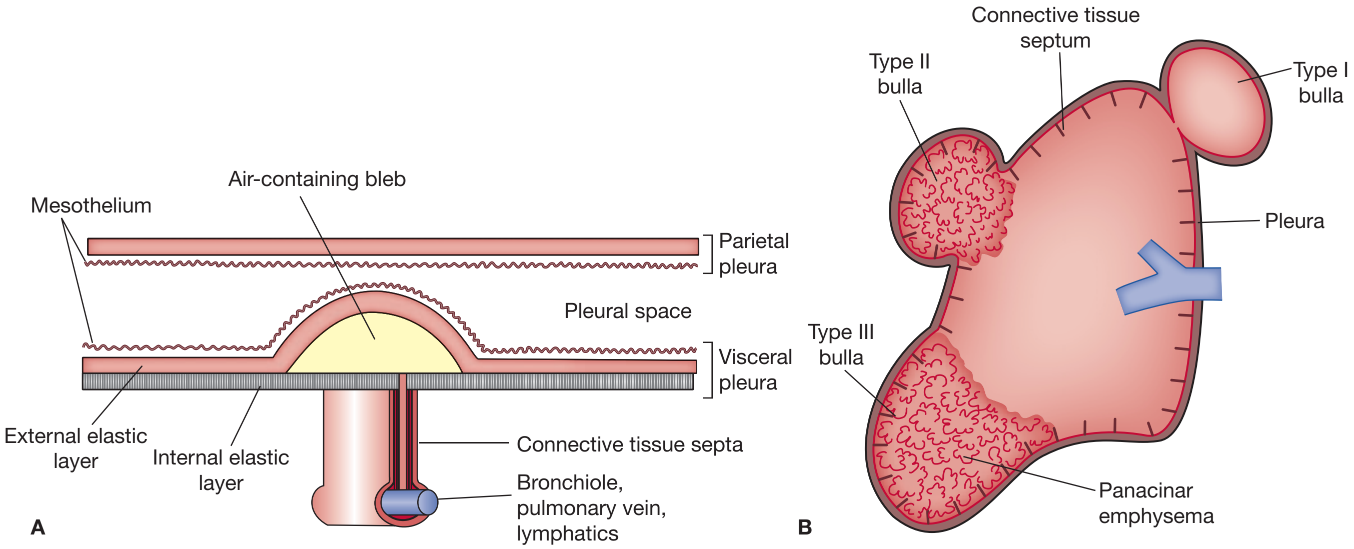

Figure 50-1 Blebs and bullae. **A.** Development of a bleb. A bleb is an accumulation of air within the pleura that is not confined by connective tissue septa within the lung. Air that escapes within the substance of the lungs makes its way to the surface, separating the internal from the external elastic layers on the visceral pleura. **B.** Different types of bullae. In contrast to a bleb, a bulla is confined by connective tissue septa of the lung and is deep to the internal elastic layer of the visceral pleura. Three different types of bullae are shown arising from a lung that has been removed from within the chest wall. A type I bulla is shown at the apex, a type II is in the middle zone, and a type III is arising at the base. The short *dark lines* denote connective tissue septa. Panacinar emphysematous parenchyma is present within the types II and III bullae. *(Adapted with permission from Reid L. The Pathology of Emphysema. Chicago, IL: Year Book; 1967.)*

  - Salla disease
  - Marfan syndrome
  - Fabry disease
  - Cutis laxa

pleural mesothelial cells on the external surface are either reduced in number or completely absent; bundles of collagen fibers lie naked and separated from one other by small pores or crevices.

Type II bullae arise from the subpleural parenchyma and are characterized by a neck of panacinar emphysematous lung tissue. The interior of these airspaces consists of emphysematous lung in which blood vessels are still present. In contrast to type I bullae, the outer wall is formed by pleura covered with intact mesothelial cells. Although connective tissue septae are present within the bullae, they are not found in the wall. Type II bullae may occur anywhere in the lung, but they are most frequent in the upper lobe, at the anterior surface of the middle lobe, and over the diaphragm. Type III bullae consist of slightly hyperinflated lung connected to the rest of the lung by a broad base extending deep into the parenchyma. This type is believed to represent an atrophic form of emphysema.

TABLE 50-2 Characteristics of Blebs, Bullae, and Cysts

	Bleb	Bulla	Cyst
Site	Within visceral pleura	Arises within secondary lobule	Lung parenchyma or mediastinum
Size	1–2 cm	1 cm to 75% of a lung	2–10 cm
Lining	Elastic laminae of the pleura	Connective tissue septa	Epithelium
Associated condition	Spontaneous pneumothorax	Bronchogenic carcinoma	Respiratory infection

PATHOGENESIS

Several hypotheses have been proposed over the years for how bullae develop, although none has been proven.[1,3,4,8] These include the following: (1) Weakness of the alveolar walls predisposes to the formation of bullae, particularly at the apices of the lungs, where pleural pressures are most negative. This theory underscores the proclivity of bullae for the upper lobes and stresses the influence of mechanical forces acting upon flawed tissue. (2) Inflammatory disease of a bronchiole leads to progressive air trapping and "tension airspaces." (3) Disordered collateral ventilation produces the findings. (4) The same mechanisms responsible for generalized emphysema are operative in the formation of bullae. (5) Underlying paraseptal emphysema produces bullous disease.

Of all the hypotheses, that of underlying paraseptal emphysema is the most popular.[1,3] The hypothesis envisages destruction of alveoli adjacent to connective septae or the pleura. The pattern relates to the fact that capillaries in alveolar walls that abut connective tissue septa are less numerous than elsewhere because of a sparse network of arterioles and arteries in peripheral alveoli. Consequently, these regions of the acinus have less vascularity and greater compliance.

Dynamic computerized tomography and intrabulla pressure measurements have raised questions about the theory that bullae are formed by positive pressure within the airspace.[1,9] The lung surrounding a bulla is less compliant than the bullae itself; accordingly, the pressure necessary to inflate the surrounding lung is greater than that necessary to inflate the bulla. The pressure within a giant bulla has been found to be the same as pleural pressure. Therefore, when a bulla and its surrounding lung are exposed to the same negative pleural pressure, the bulla fills preferentially and completely like an inflated paper bag, prior to the surrounding lung inflating. Further inspiration increases the elastic recoil pressure, thereby exerting a greater retractive force on the lung parenchyma and enlarging the airspace. Nevertheless, bullae can be removed from within the lung while still maintaining their volume, indicating a positive intra-bulla pressure.

Bullae within the intact chest are molded and compressed to fit adjacent anatomic configurations. However, if the lung is released from these constraints (e.g., when removed from the chest cavity), bullae project as shiny bubbles at the lung surface (Fig. 50-2). Within the thoracic cavity, large bullae cause crowding of adjacent lung parenchyma, and structures such as bronchi are displaced, stretched, and narrowed over the bullae surfaces. Very large airspaces can expand across the midline or even extend into the neck. Bullae represent more than just overexpanded alveoli because the remnants of bronchioles and their accompanying vessels sometimes persist as trabeculae within the bullae. Interlobular septae can be incorporated into the wall as the airspace expands from within the secondary lobule.

Two important risk factors for bullous emphysema are cigarette smoking and α_1-antitrypsin deficiency. Many patients with bullous emphysema are cigarette smokers, and most bullous lesions are associated with paraseptal or centriacinar emphysema. Although bullous emphysema is typically found in young males, elderly patients with α_1-antitrypsin deficiency who are lifelong nonsmokers may develop bullous changes in later life. A hereditary predisposition to bullous emphysema is also suggested by its association with a variety of rare familial disorders, including Fabry disease, Salla disease, cutis laxa, Ehlers–Danlos syndrome, and Marfan syndrome.[1] Giant bullous emphysema has also been reported with histologic changes of placental transmogrification—a rare, benign lung disease of unknown etiology in which the lung shows bullous changes or, rarely, cysts or nodules.[10,11] Lung pathology demonstrates papillary structures similar to placental villi surrounding the pulmonary epithelium. The tight skin mouse, which has a dominant mutation for

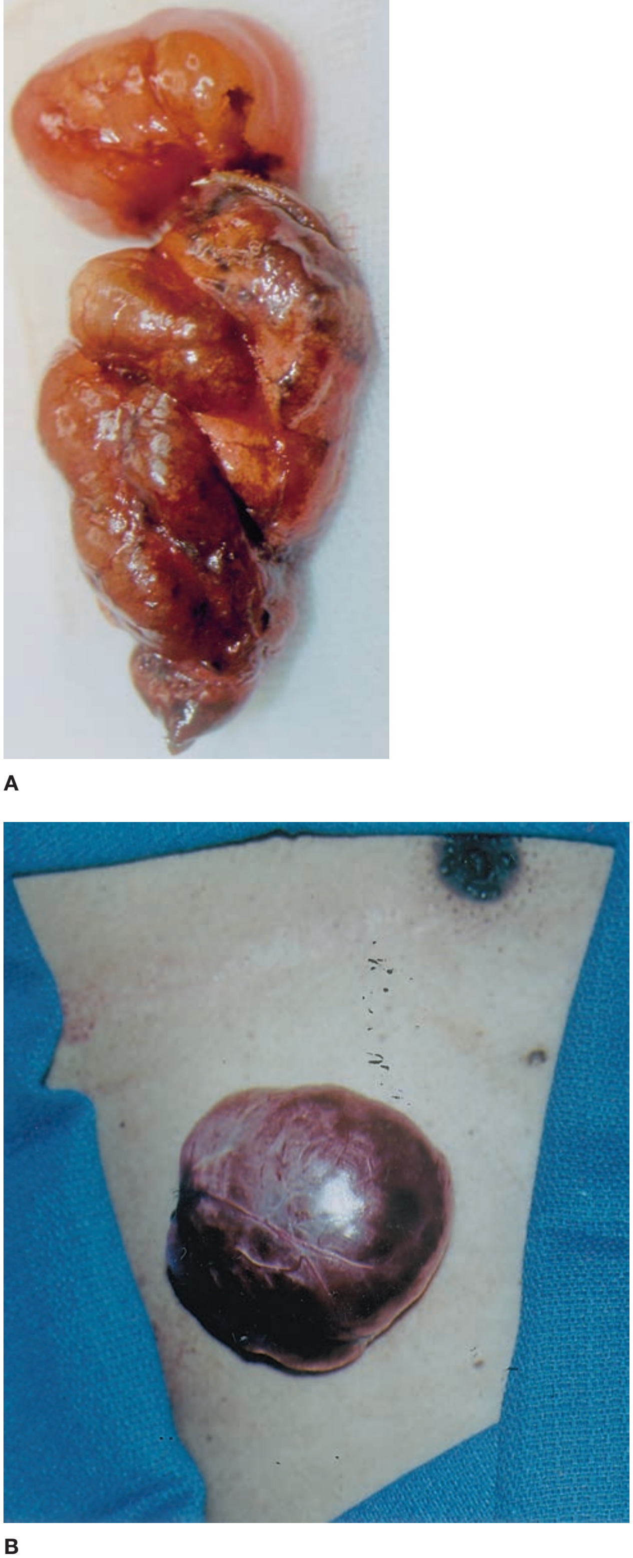

Figure 50-2 **A.** Surgically resected specimen with a bulla projecting from the lung surface. **B.** A bulla is shown projecting through a previous chest tube insertion site onto the surface of the skin.

the elastase gene and is characterized by multiple connective tissue abnormalities, serves as a unique model for bullous emphysema.[12]

DISTRIBUTION OF BULLAE

As noted previously, the tendency for bullae to occur in the upper lobes is usually attributed to the greater mechanical stresses imposed on the lung apices than bases. Because intrapleural pressure near the lung apices is more negative than at the bases, apical alveoli are subjected to greater expanding stresses than are basal alveoli. Radioactive gas studies and in situ freezing techniques have demonstrated that alveoli in the upper lung zones are considerably larger than those in the lower zones. Gravity also plays a role, as the upright lung behaves like a coiled spring, which, when allowed to dangle in the upright position, shows larger gaps between coils at the top than the bottom.

Engineering techniques used to study the distribution of stresses in aircraft have been applied to the analysis of stresses on the lung.[1] These have shown that the larger expanding stresses at the apices are directed primarily in a vertical direction, and to a lesser extent, laterally. The stresses tend to increase with expansion of the lung, but they are present also when the lung volume decreases below functional residual capacity (FRC). The increase in apical stress at low lung volumes has been attributed to an increase in the rigidity of the lungs as residual volume is approached.

EVALUATION AND DIAGNOSIS

In asymptomatic individuals, bullae may be detected during routine chest radiography. Small bullae rarely become visible on the chest radiograph but are usually easily visible by computed tomography (CT). As a rule, small bullae usually produce no symptoms, signs, or discernible alterations in pulmonary function.[13] However, rupture of one or more bullae may lead to spontaneous pneumothorax (see below). In some patients bullae give rise to progressive dyspnea or chest pain (Fig. 50-3A,B).[14] On occasion, a patient with bullous lung disease develops sudden, severe breathlessness secondary to development of a spontaneous pneumothorax[15,16] or sudden increase in bulla size due to air trapping. In patients with known bullous disease, infection in a bulla can occur (see below). Radiographically, infection is usually identified by the appearance of an air–fluid level (Fig. 50-4A–C).[5,6,8,9] The physical findings in a patient with one or more bullae usually reflect the overall state of the lungs. Only infrequently do giant bullae reach a size sufficient to cause a localized decrease in regional air entry, with absent breath sounds and increased resonance to percussion; this process can be associated with the "vanishing lung syndrome."[17]

Laboratory

Routine laboratory testing in the evaluation of bullae includes the measurement of hemoglobin and hematocrit to identify if anemia is contributing to respiratory symptoms and to assess for possible secondary polycythemia due to chronic hypoxemia.[1,14] Measuring an α_1-antitrypsin level should be obtained to diagnose α_1-antitrypsin deficiency.[18] Finally evaluation of arterial blood gases, performed while the patient is breathing room air if possible, is generally indicated in patients with severe respiratory insufficiency and those being evaluated for possible bullectomy.[14] As noted in Table 50-3, a Pa_{CO_2} greater than 45 mm Hg is considered a relative contraindication for bullectomy.[19]

Imaging

Imaging techniques employed in the evaluation of bullous lung disease include routine chest radiography, computed tomography, and nuclear medicine modalities.

Chest Radiography

Although routine chest radiography is the most practical method for identifying the presence of bullae, the technique generally discloses less than 50% of bullae identified on CT.[20] In a given patient, serial radiographs taken over years are invaluable in tracing evolution of the disease.[13] The presence of the condition is suggested by

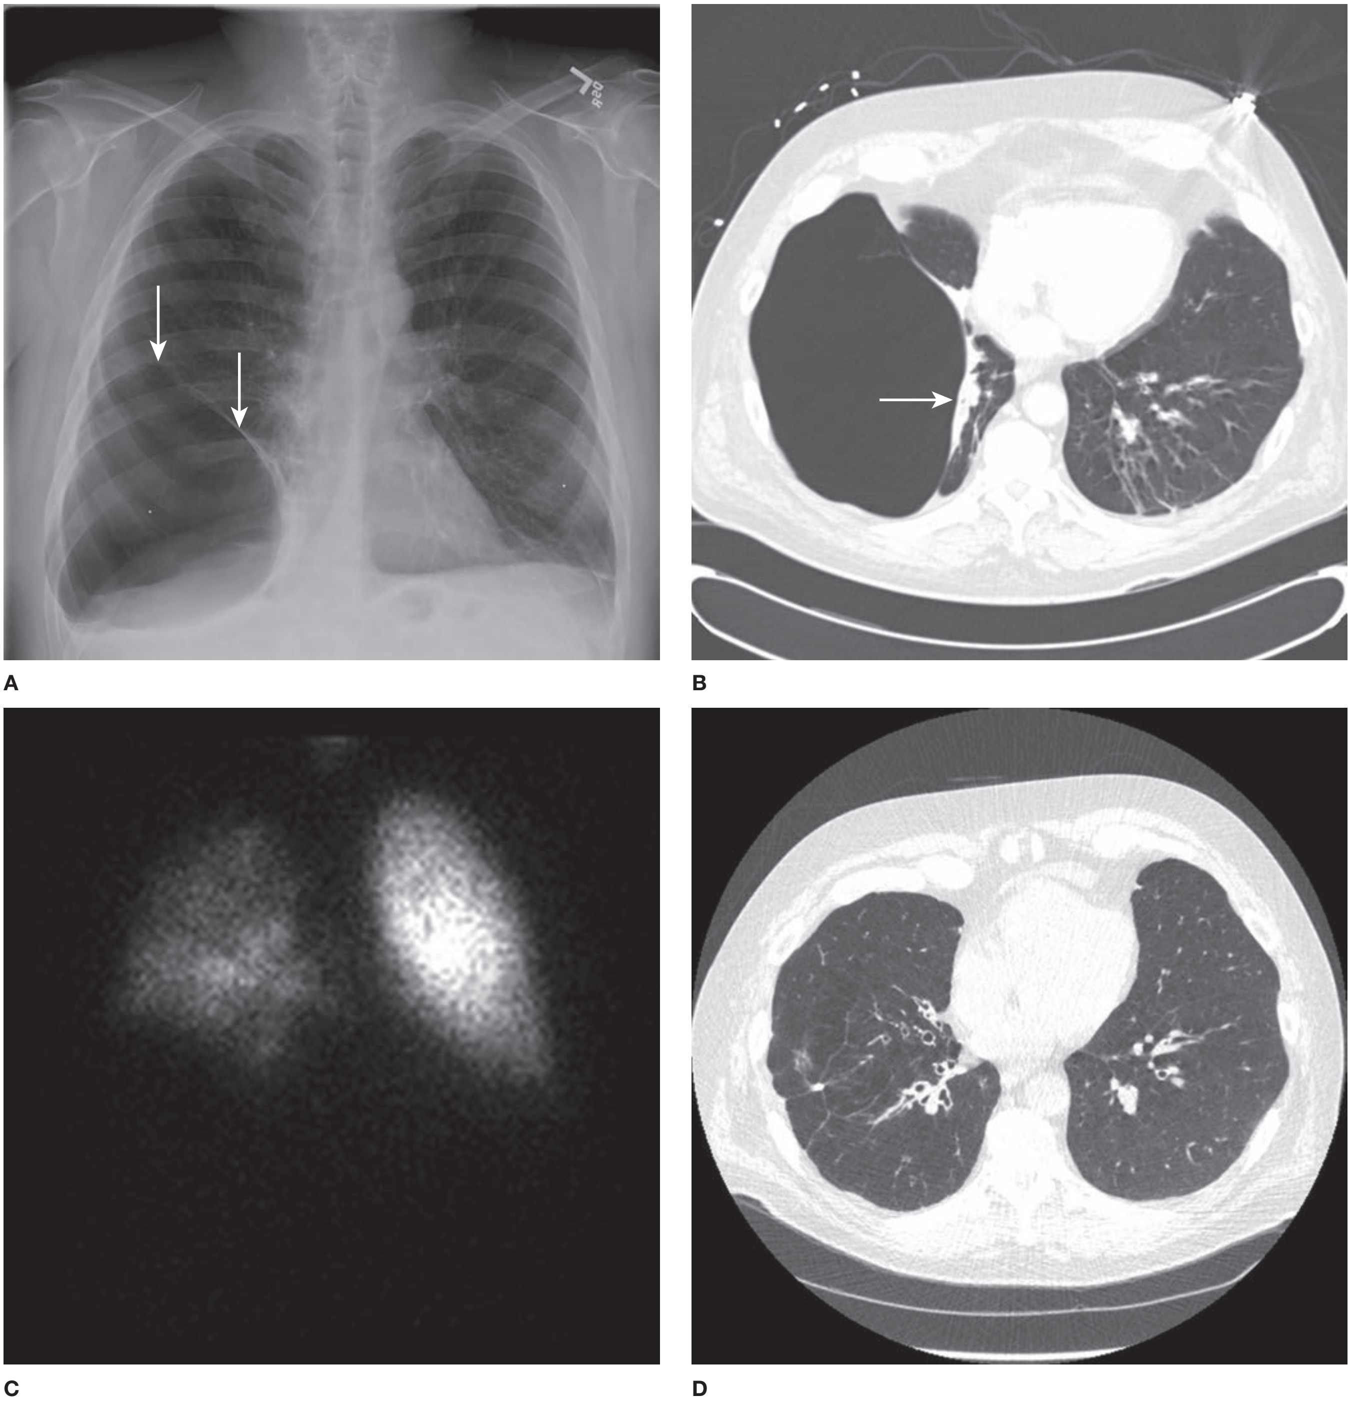

Figure 50-3 **A.** Chest radiograph demonstrating a right lower lobe bulla. Note the demarcating lines, or "hairline shadows" *(arrows)*. **B.** CT image of the lungs demonstrating the right lower lobe bulla with compressed lung *(arrow)*. **C.** Perfusion scintigraphy demonstrating decreased perfusion to the right lower lung zone. **D.** CT image of the lung following surgical resection of the right lower lobe bulla.

areas of increased radiolucency that are sharply delineated by fine radiopaque lines representing the walls of the bullae. These lines, or "hairline shadows," are composed of compressed and fused interlobular septae or pleura.[16] Because the hairline shadows appear incomplete on the chest radiograph, they delineate only segments of the bulla wall (Fig. 50-3A). Distinction between hairline shadows produced by a bulla, and thicker, sometimes irregular, walls of a cavity is usually not difficult. More difficult is distinguishing bullae from cysts. The presence of other radiologic signs of emphysema or fibrotic lung disorders suggests that the cystic structure is a bulla.[15] Similarly, distinguishing between a large bulla and pneumothorax may be challenging.[14,21,22] In general, the pleural line associated with a large bulla is usually concave relative to the lateral chest wall, whereas the pleural line associated with a pneumothorax is convex relative to the lateral chest wall.[14] Similarly, observation of the "double-wall sign" (i.e., the presence of air on both sides of the bulla wall) may be helpful in identifying the findings as due to a bulla.[16]

A chest radiograph obtained after forced expiration is sometimes helpful in demonstrating the presence of bullae: air trapping during the expiratory maneuver accentuates their outline by preventing a decrease in their size as the surrounding lung empties.[4] Large bullae

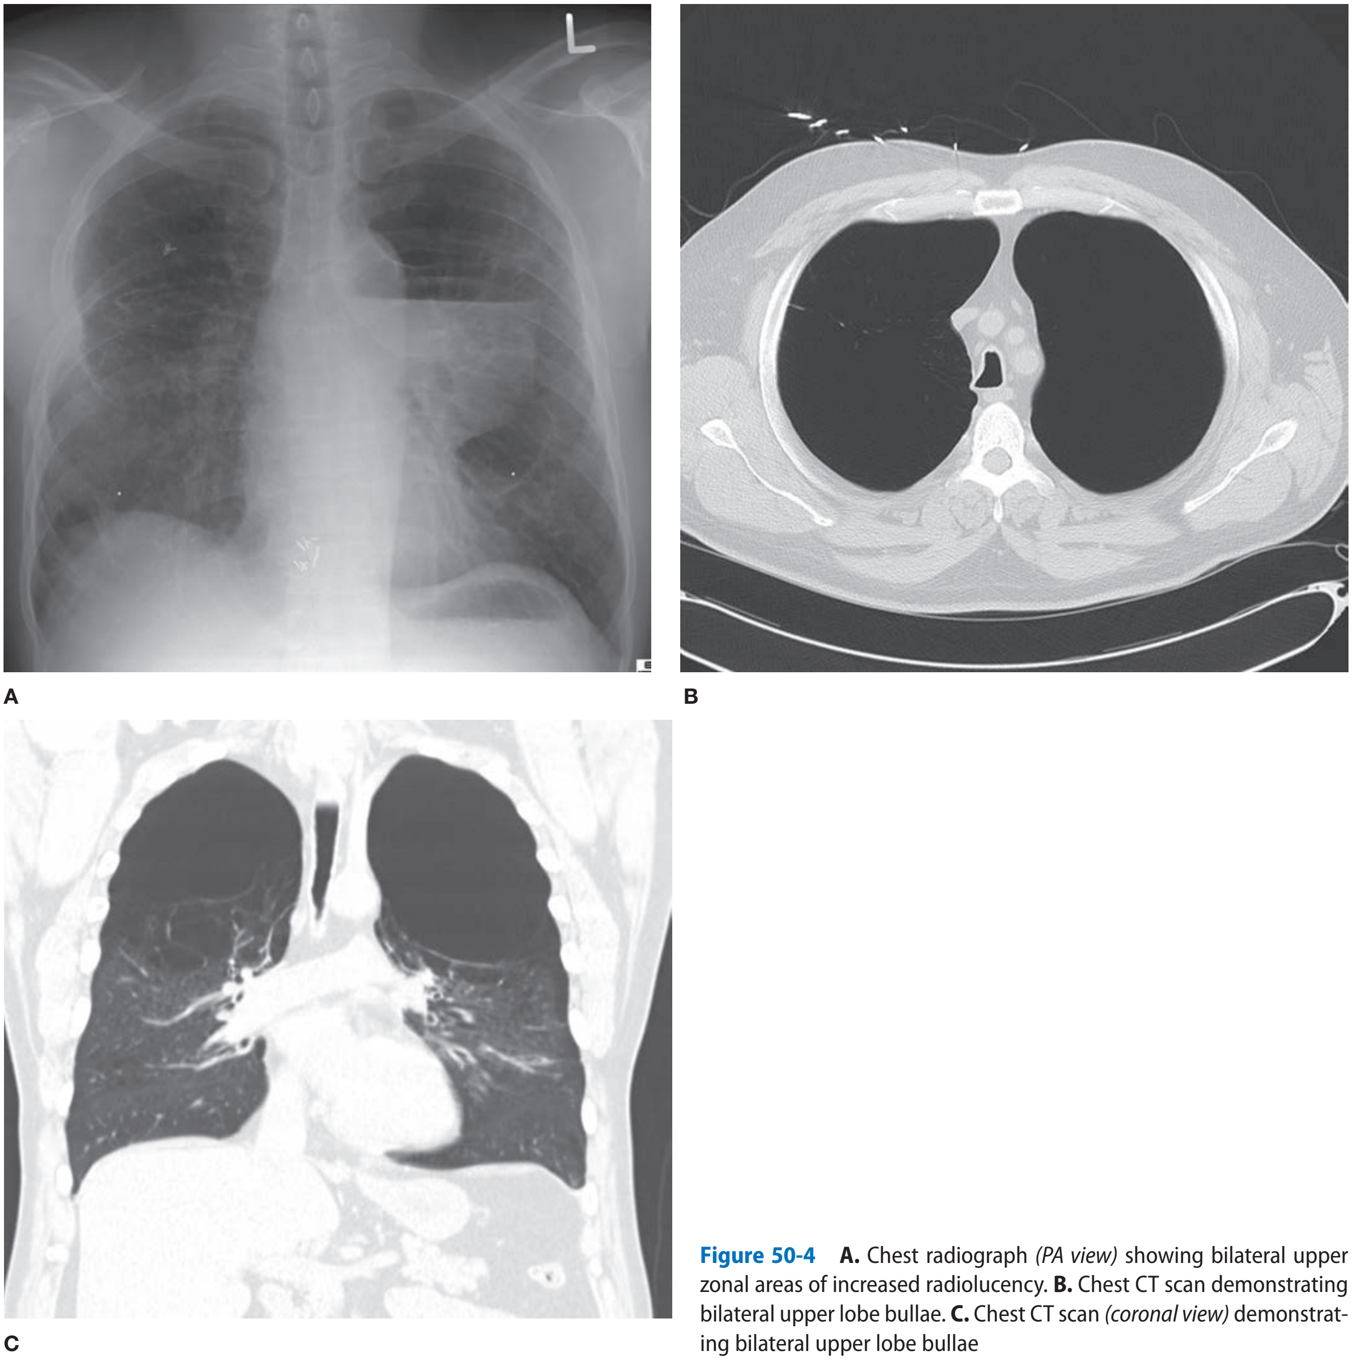

Figure 50-4 **A.** Chest radiograph *(PA view)* showing bilateral upper zonal areas of increased radiolucency. **B.** Chest CT scan demonstrating bilateral upper lobe bullae. **C.** Chest CT scan *(coronal view)* demonstrating bilateral upper lobe bullae

sometimes displace the mediastinum contralaterally and may even compress the opposite lung.

Computed Tomography

CT provides valuable anatomic information about the size, number, and relationships of bullae, as well as crowding of adjacent lung and disposition of the pulmonary vasculature (Fig. 50-3B).[17,23,24] Bullae are identified as areas of radiolucency that usually do not contain blood vessels and that are confined by visible walls. High-resolution computed tomography (HRCT) shows that large bullae are frequently associated not only with distal acinar (paraseptal) emphysema, but also with centriacinar emphysema—the type of emphysema usually associated with cigarette smoking.[17] These observations are consistent with the hypothesis that peripheral airspaces in paraseptal emphysema may coalesce to form larger bullae that may crowd normal adjacent lung. In addition, CT has shown that when bullae occur in the context of generalized emphysema, the extent of bullous emphysema correlates poorly with measurements of pulmonary function, and that the main determinant of respiratory function is the severity of emphysema in the bullous-free parts of the lung.[25] On chest CT, giant bullae are predominantly located in the upper lobes and are generally subpleural.[14] However, in patients with α_1-antitrypsin deficiency, bullae are most commonly located at the lung bases. Approximately half of the patients have bilateral bullae (Fig. 50-4), and, occasionally, deviation of the mediastinal structures to the contralateral side may be noted.[14] CT has been used to create three-dimensional reconstructions of bullae, which can then be used to calculate bullae volumes (Fig. 50-5).

Nuclear Imaging

Lung scanning using radionuclide-based techniques may provide useful preoperative information in evaluating patients with bullous

TABLE 50-3 Potential Indications and Contraindications for Classical Bullectomy

Parameter	Indications	Contraindications
Clinical	Young age (<50 years) Rapid progressive dyspnea despite maximal medical therapy Ex-smoker	Age >50 years Comorbid illness Cardiac disease Pulmonary hypertension >10% weight loss Frequent respiratory infections—chronic bronchitis Ongoing tobacco use
Physiologic	Normal or slightly ↓ FVC FEV$_1$ >40% predicted Little bronchoreversibility "High" trapped lung volume Normal or near-normal D$_{LCO}$ Normal Pa$_{O_2}$ and Pa$_{CO_2}$	FEV$_1$ <35% predicted "Low" trapped gas volume Decreased D$_{LCO}$
Imaging	*CXR*—bulla >1/3 hemithorax *CT*—large and localized bulla with vascular crowding and normal, compressed pulmonary parenchyma around bulla *Angiography*—vascular crowding with preserved distal vascular branching *Isotope scan*—well-localized matching defect with normal uptake and washout for underlying lung	*CXR*—vanishing lung syndrome Poorly defined bullae *CT*—multiple ill-defined bullae in underlying lung *Angiography*—vague bullae; disrupted vasculature elsewhere *Isotope scan*—absence of target zones, poor washout in remaining lung

lung disease.[26] A lung perfusion scan provides a semiquantitative assessment of regional blood flow (Fig. 50-3); results of ventilation scans vary with the technique. A single-breath scan using ^{133}xenon often fails to demonstrate ventilation of a bulla, whereas a continuous ventilation scan often shows slow filling and emptying of the structure.[26,27] Complete lack of communication between the airways and bulla is reflected in the absence of filling during all phases of the continuous ventilation scan.

■ Pulmonary Physiology

Clinical evaluation of bullous lung disease is aided by assessment of pulmonary function, pulmonary mechanics, exercise performance, and the pulmonary circulation.

Pulmonary Function Tests

Pulmonary function tests have considerable practical value in distinguishing between individuals with localized bullae in whom intervening lung is normal (bullous disease), and those in whom localized bullae are part of obstructive airways disease (bullous emphysema) (Table 50-4).[14] The distinction is important, since those with obstructive airways disease are generally poor surgical candidates because of impaired pulmonary function. In individuals with bullous disease, the volume of air in the lungs can be estimated using plain radiography, CT, body plethysmography, or other pulmonary function test methods for determining lung volume, including closed circuit (helium dilution) and open circuit (nitrogen washout) techniques.[14,19] The volume of air trapped in a bulla can be determined as the difference between the functional residual capacities determined plethysmographically and by open or closed circuit methods (Table 50-4). This difference is due to the relative inability of the inert gas used in the circuit methods to enter the bulla.

Pulmonary Mechanics

Distinction between widespread obstructive airways disease with concomitant bullae and bullous lung disease has practical significance, since surgical lung resection in generalized emphysema offers a less certain therapeutic response than does resection of giant bullae in the absence of widespread obstructive lung disease (Table 50-3).[14] As large bullae expand, they initially cause relaxation of adjacent elastic lung tissue; with continued expansion, adjacent lung is compressed. Relaxation of the surrounding pulmonary parenchyma results in a decrease in radial traction on airways, thereby increasing air flow resistance. The effects of bullectomy on respiratory mechanics are inconsistent. Generally, resection of a large bulla increases lung static elastic recoil (by allowing for decompression of elastic lung parenchyma) and decreases airways resistance.

The diffusing capacity, rather than lung elastic recoil, is usually determined to aid in distinguishing between widespread emphysema and localized bullae, as more widespread loss of alveolar surface area in emphysema reduces the DL_{CO}; indeed, the diffusing capacity correlates better with morphologic estimates of emphysema than do most other tests.[14,19] Although the combination of a decreased DL_{CO} and reduced static elastic recoil pressure favors the diagnosis of widespread emphysema rather than localized bullae, both measurements may also be decreased by bullae that compress adjacent normal lung (Table 50-3).[4] Respiratory muscle strength, assessed by measurements of maximal inspiratory and transdiaphragmatic pressures, improves after bullectomy in some patients with bullous emphysema.[28]

Exercise Testing

In patients with a few circumscribed bullae and otherwise normal lungs, exercise testing reveals that the alveolar–arterial difference in Pa_{CO_2}, ratio of dead space to tidal volume, diffusing capacity, and arterial oxygenation remain normal or near normal with exercise.[14] On the other hand, in patients in whom bullae are associated with panacinar emphysema, the alveolar–arterial difference in Pa_{CO_2} is widened at rest and during exercise.[29] The latter group of patients also may develop arterial hypoxemia during exercise. The Pa_{CO_2} tends to hover around the upper limit of normal at rest and during exercise, and the ratio of dead space to tidal volume is higher than in patients with normal intervening lung. The steady-state diffusing capacity is also reduced and fails to increase normally during exercise. Patients in whom bullae are associated with chronic bronchitis also show a widened alveolar–arterial difference in Pa_{CO_2} and an increase in the ratio of dead space to tidal volume at rest. However, in these patients the decrease in Pa_{CO_2} during exercise is modest, even though the Pa_{CO_2} at rest is abnormally high and increases further during exercise (indicating progressive alveolar hypoventilation).[3]

Pulmonary Circulation

In general, resting pulmonary arterial pressure and blood flow are within normal limits in patients with bullous lung disease (i.e., the bullae act like "amputated" segments of lung); the volume of the vascular bed available for recruitment as cardiac output increases is limited.[1,3] However, in patients in whom bullous disease has severely reduced the extent of the pulmonary vascular bed, pulmonary arterial pressure may be elevated at rest and during exercise; in a few instances, pulmonary hypertension and cor pulmonale may be observed.[1,3] Exercise in bullous lung disease is generally associated with an excessive increase in pulmonary arterial pressure, as increases in pulmonary blood flow are not effectively accommodated by the restricted vascular bed.[3] Underlying pulmonary disease further exaggerates the increase in pulmonary artery pressure during exercise.

COMPLICATIONS

The major complications of bullous lung disease are fluid accumulation (including infection) in the bulla, spontaneous pneumothorax, bronchogenic cancer, chest pain, and hemoptysis.

■ Fluid Accumulation

The determination that an air–fluid level is within a bulla and not in a newly formed cyst or cavity is generally based on the new appearance of fluid in a previously known bulla or the presence of other bullae.[14] CT of the chest is indicated to assure that the air–fluid level is within a bulla and to identify any surrounding pneumonia, adjacent pulmonary nodule, or an increase in wall thickness of the bulla. The latter aids in differentiating an air–fluid level within a bulla from other disorders such as tuberculosis, fungal disease, lung abscess, or cavitary bronchogenic lung cancer (Fig. 50-6). These processes typically have substantially thicker cavity walls. The presence of a fluid level within a bulla, especially if the bulla is located subpleurally, occasionally prompts the mistaken diagnosis of a loculated hydropneumothorax. CT is helpful in separating these two conditions.

Benign, Sterile Bullous Fluid

Benign, sterile fluid accumulations in a bulla can result from adjacent pneumonia or from poorly functioning bronchial communications with inadequate drainage of normally accumulating fluid.[30] In asymptomatic patients who have a thin-walled bulla without chest CT evidence of an adjacent pneumonitis or nodule, continued observation without specific therapy is appropriate.[5] Close radiologic evaluation is typically performed at 6- to 12-week intervals to ensure that an infection or bronchogenic carcinoma is not present. In patients with clinical and radiographic evidence of adjacent pneumonia antibiotic therapy is indicated.[31] The air–fluid level may persist for weeks to months after resolution of active infection.

■ Infected Bulla

A superinfection within a bulla can occur with clinical manifestations including fever, cough, purulent sputum production, dyspnea, and pleuritic chest pain. Laboratory findings may include leukocytosis and positive sputum cultures. When clinical and radiographic findings suggest an infected bulla, empiric antibiotics should be initiated based on a regimen similar to that used for community-acquired pneumonia in a patient with COPD.[5,14] Bacterial species that have been identified from infected bullae include methicillin-resistant *Staphylococcus aureus* (MRSA), *Bacteroides*, *Pseudomonas aeruginosa*, and mycobacteria.[32–34] Treatment is sometimes prolonged and may require parenteral or intrabulla administration, since poor drainage of the bulla inevitably slows resolution of the disease process.[35] The course of the infection should be followed by interval chest radiographs, in part as bulla infection has been associated with bronchogenic cancer.[36] If a patient does not improve with empiric antibiotics, percutaneous aspiration of bullous fluid can be performed under CT guidance to confirm the presence of infection and to identify the antibiotic sensitivities of the infecting organism.[5,32] It should be recognized that percutaneous aspiration carries an increased risk of pneumothorax and empyema.[14] Tube thoracostomy[37] and endoscopic drainage also have been utilized.[38]

■ Pneumothorax

Spontaneous pneumothorax may be a complication of paraseptal emphysema, particularly in patients who continue to smoke. The typical presentation is a sudden onset or worsening of dyspnea with or without pleuritic chest pain. Ultrastructural assessments suggest the possibility of air leaking through the wall of the bullae with sloughing of mesothelial cells,[39] while lung density measures suggest a valve-like effect with air trapping.[40] A few case reports have described a pneumothorax occurring when a bronchogenic carcinoma eroded through the wall of a bulla.[41] Tube thoracostomy drainage of pleural air is often required; this depends on the size of the pneumothorax and the degree of respiratory impairment.[14,42,43] Patients with ruptured bullae also tend to have prolonged air leaks, along with pleural and parenchymal infections. Subsequent management is directed at preventing recurrence. For patients with a bulla and a secondary spontaneous pneumothorax, pleurodesis using mechanical abrasion of the pleura via video-assisted thoracoscopic surgery (VATS) can be considered.[41,43,44] For patients with minimal surrounding diffuse emphysema, a bullectomy can be performed at the time of pleurodesis; for those with diffuse bullous emphysema, pleurodesis is often performed without bullectomy.[14]

■ Bronchogenic Cancer

Primary lung cancer has been reported to be associated with bullous lung disease.[45–48] Presenting manifestations include pneumothorax and hemoptysis.[48] The increased incidence of lung cancer may be due to the fact that lung cancer occurs more frequently in fibrotic lungs which are, themselves, predisposed to development of bullae.[1] Other explanations for the increased incidence of malignancy include dystrophic changes in lung parenchyma caused by bullous disease or persistence of carcinogens in poorly ventilated bullae.[1] The CT appearances for bronchogenic cancer complicating bullae include a nodule or mass extruding from the wall of the bulla, a nodule or mass confined within the lumen, a soft tissue density thickening the wall of the bulla, a pneumothorax, and an air–fluid level.[39,49–52] A proposed classification system for these malignancies includes four types, including a nodule abutting a cyst wall, a nodule arising from the cyst wall and protruding into the cyst lumen, a soft tissue density extending or thickening the cyst wall, and a multicystic aspect.[53] A case series with longitudinal CT findings noted that cystic airspaces developed wall thickening and/or a mural nodule after a median of 35 months.[45] A separate report noted that some cystic airspaces can develop in the location of a previous lung nodule.[54] The importance of all these features is reflected by recent reports that lung cancer detection error has been associated with failing to appreciate the importance of a linking cystic lung disease with bronchogenic carcinoma.[55,56]

■ Chest Pain and Hemoptysis

Chest pain may occur with a bulla and is attributed to overdistention of the structure.[14] The pain is angina-like and located retrosternally. The symptom is sometimes so severe as to constitute an indication for surgical intervention. Hemoptysis, which is occasionally massive, can result from rupture of blood vessels within the walls of bullae.[57]

TREATMENT

Many patients with bullous lung disease can be managed medically.[58] Because the natural history of a bulla is unpredictable, patients with

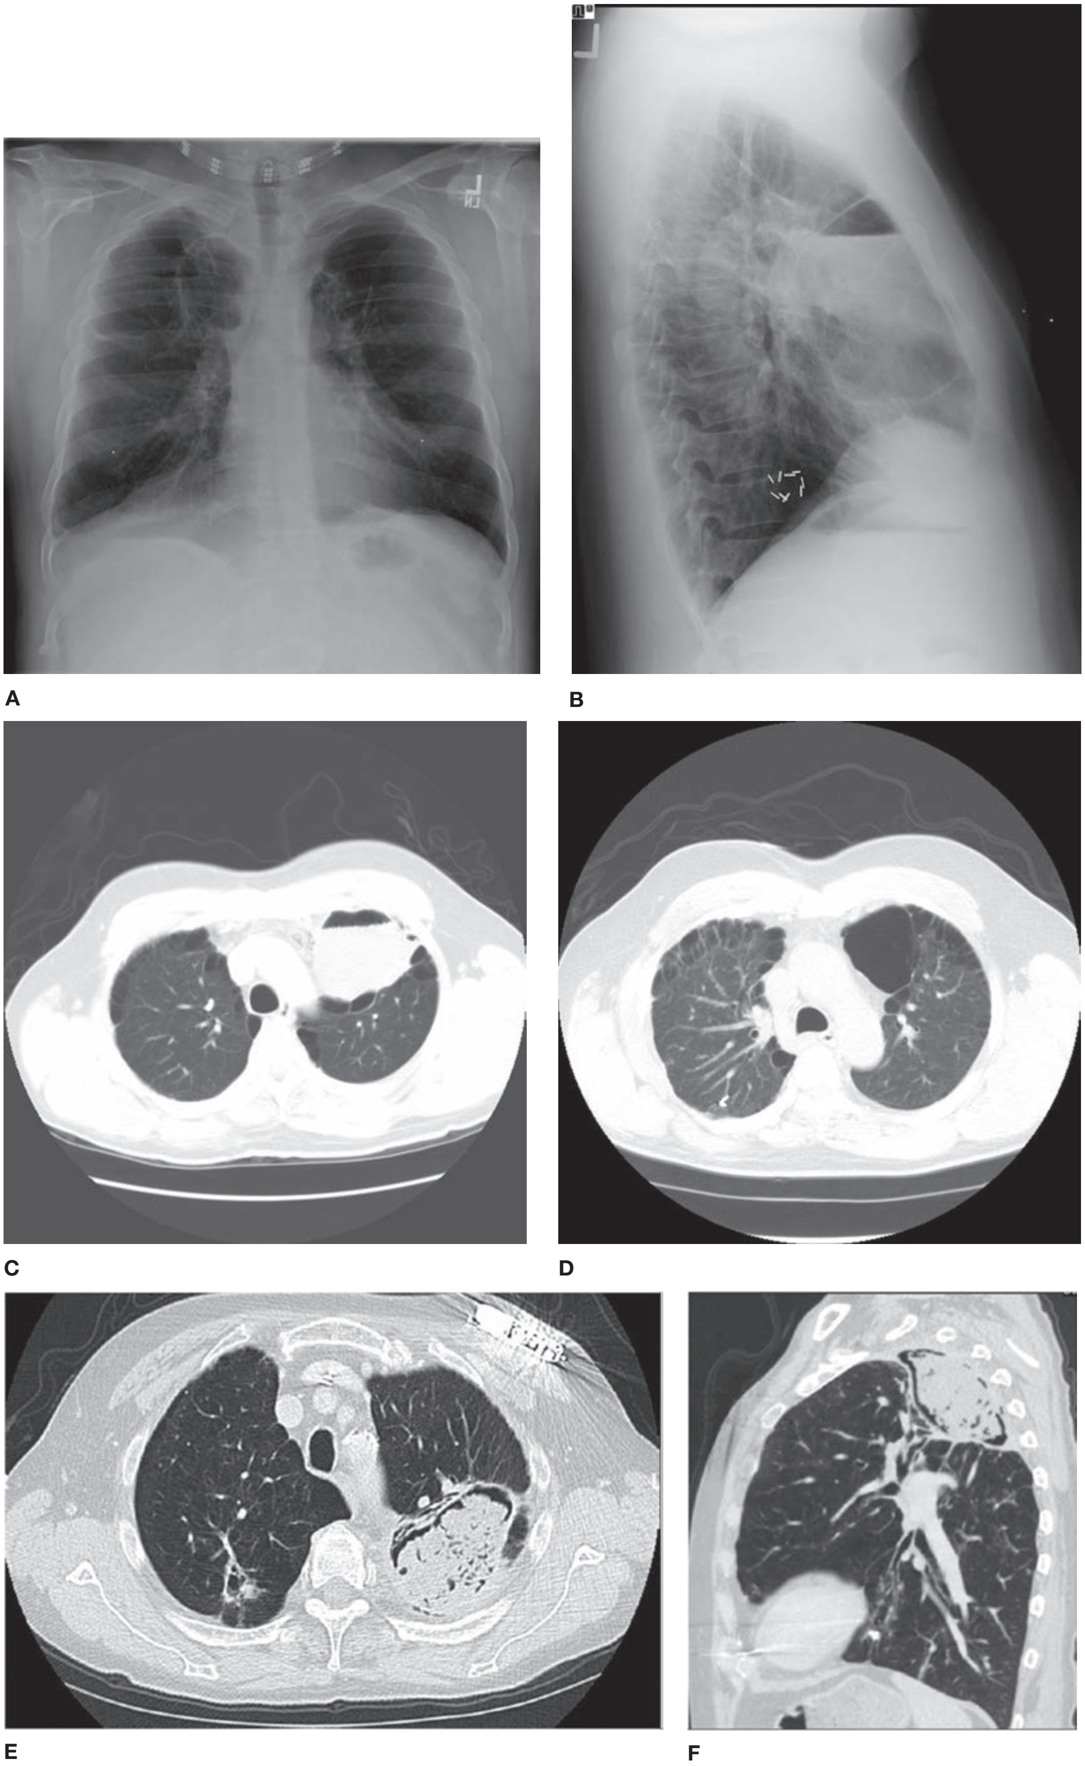

Figure 50-6 **A.** AP chest radiograph demonstrating an air–fluid level in a left upper lung bulla. **B**. Lateral chest radiograph demonstrating air–fluid level in a left upper lung bulla. **C**. CT image of the infected left upper lobe bulla. **D.** CT image of the same bulla after a prolonged course of antibiotics. **E.** CT axial view in patient with pre-existing bulla developing a fungus ball. **F.** CT sagittal view of the same patient with pre-existing bulla developing a fungus ball.

bullous disease should be monitored by chest radiography at regular intervals to ensure that the disease is stable. Occasionally, bullae enlarge suddenly and rapidly for no apparent reason; alternatively, they may shrink or disappear.[52,59,60]

■ Medical Management

The finding of a bulla in an asymptomatic patient calls for reassurance, a recommendation for annual chest radiography, advice to stop smoking, and an alert to the need for a prompt visit to a physician should symptoms develop. Activities that promote rupture of bullae (e.g., contact sports, altitude, and scuba diving) should be carefully considered.[1,61,62] Chronic bronchitis, asthma, or emphysema associated with bullae require treatment in their own right. For patients with α_1-antitrypsin deficiency augmentation therapy with antiproteases may be appropriate.[63] Endobronchial therapy with endobronchial valves (see Chapter 34) has been recently reported.[64–66]

■ Bronchoscopic Management

Over the last years bronchoscopic approaches to lung volume reduction have proved beneficial in patients with emphysema.[67] The available systems block inspired air entry into the treated lobe while air and secretions escape during exhalation. As such, valve treatment is generally reserved in patients without significant collateral ventilation to allow therapeutic lung collapse.[67] For some practitioners the presence of a large bulla has been considered problematic in this setting.[67] An increasing number of reports or small series have suggested that endobronchial therapy can be used to treat bullous disease.[64–66,68–71] One of the larger published series provides additional physiological and clinical insights.[72] In 27 consecutive patients with giant emphysematous bullae undergoing endobronchial valve therapy, 6 did not experience therapeutic collapse while 21 did; in those who experienced collapse there was little difference between lung volume measured with gas dilution technique compared with whole body plethysmography.[72] These data support that an open bulla, where endobronchial therapy would allow emptying of the treated lung, is required for optimal benefit in addition to established criteria for anatomic distribution and lack of collateral ventilation.[72] Additional, prospective comparative data are required to better define this less invasive therapeutic technique.

■ Surgical Management

Although randomized trials of giant bullectomy have not been performed, the potential benefits of elective bullectomy have been described in a number of case series.[19,73] In general, significant symptomatic and functional improvements have been reported for 5 or more years in 60% to 90% of patients.[19,73] Patients with diffuse emphysema tend to deteriorate faster than patients without diffuse emphysema.[73] A systematic review of bullectomy reported that hypoxemia was more likely to improve compared with spirometric parameters or diffusing capacity (DL_{CO}).[73] Patients with radiographic evidence of compressed lung were the most to likely experience improved oxygenation.[73] Perioperative mortality ranges from 0% to 7% for bullectomy via open thoracotomy; patients with diffuse emphysema seem to experience a higher mortality rate.[73] Causes of death include pneumonia, respiratory failure, pulmonary embolism, and cardiovascular complications.

Indications

The most common indication for bullectomy is severe dyspnea due to a bulla occupying 30% of more of the hemithorax or spontaneous secondary pneumothorax.[24,74,75] A key challenge for the clinician is selecting the optimal patient for bullectomy. A key factor suggesting that bullectomy may be beneficial is a bulla that occupies greater than 50% of the hemithorax with radiographic evidence that the bulla is compressing adjacent normal pulmonary parenchyma (Table 50-3; Fig. 50-3A,B).[19,76] An overall enumeration of criteria reported to define patients who are most likely to benefit from bullectomy is presented in Table 50-3.

As noted in Table 50-3, physiologic data have been reported to provide valuable information in guiding the decision to perform bullectomy. The majority of patients who undergo bullectomy have an FEV_1 less than 80% predicted but greater than or equal to 40% predicted; these thresholds have been supported by case series.[74] Similarly, patients likely to benefit have physiologic evidence of air trapping (e.g., total lung capacity [TLC] >100% predicted, residual volume [RV] >150% predicted).[77] Some have suggested that the difference in lung volume measured by body plethysmography versus helium dilution techniques can be compared to estimate the volume of nonventilated lung. A larger nonventilated volume suggests a more favorable response to bullectomy.[19,76]

Contraindications

As noted in Table 50-3, features associated with a less favorable result following bullectomy include older age, ongoing cigarette smoking, significant comorbid disease, lower pulmonary function (FEV_1 and DL_{CO}), hypercapnia, poorly defined bullae on chest imaging, and pulmonary hypertension.[73,74,77–83] Similarly, patients with chronic sputum production or frequent lung infections have been suggested to be less likely to improve.[73]

Preoperative Evaluation and Management

The preoperative evaluation for bullectomy includes pulmonary function testing and imaging as noted earlier. Underlying COPD should be treated aggressively with an appropriate combination of inhaled medications and pulmonary rehabilitation. Preoperative cardiac evaluation is appropriate given the increased risk of cardiovascular comorbidity among patients with COPD.[84]

Anesthetic Management

Standard monitoring during the procedure includes blood pressure, pulse oximetry, capnography, core temperature, and continuous electrocardiography.[85] Arterial and central venous pressure monitoring are not mandatory but frequently utilized. Bullectomy is typically performed under general anesthesia.[85] Short-acting anesthetic agents are preferred over longer-acting agents to facilitate early extubation.[85] Intravenous agents are typically used for induction of anesthesia, as severe bullous disease may make the uptake and distribution of inhalational agents erratic.[85] A thoracic epidural catheter is usually placed for administration of epidural anesthetic agents during and/or after surgery.[85]

After anesthetic induction, appropriate positioning, and sterile draping, an endotracheal tube that allows isolation of ventilation to one lung is placed to administer single lung ventilation to the nonoperative lung and to enable deflation of the operative lung.[85] Immediately postoperatively patients are assessed for anemia, cardiac ischemia, electrolyte abnormalities, hypercapnia, hypoxemia, and inadequate lung reexpansion.[85] If these factors are acceptable, the patient may be extubated; in the majority of cases this occurs in the operating room.[86]

Operative Approach and Techniques

Although many surgeons prefer an open approach for bullectomy, there is increasing application of VATS techniques.[77,87–90] When an open thoracotomy is performed, the posterolateral approach is generally used for unilateral bullous disease, while median sternotomy is often utilized for resection of bilateral bullae.[77] The amount of lung resected in addition to the main bulla is dependent on a balance between removing diseased tissue to optimize re-expansion of compressed tissue while avoiding resecting healthy lung tissue and minimizing prolonged air leak around the suture line.[24,73] For a single bulla that is well demarcated and has a clear, narrow pedicle, a simple stapled excision is adequate. When the bulla is broad based or when numerous bullae merge indistinctly, a broad stapled wedge resection is usually necessary.[86] Lobectomy and segmentectomy may be utilized in unusual settings.[75,77,91] Thoracoscopically treated patients who are smokers and suffer from concomitant emphysema suffer greater postoperative complications.[90]

Ablation or excision of bullae can be achieved by a variety of surgical methods, including plication, laser ablation, and excision with a stapler.[24] The latter is the most frequently utilized. Numerous approaches are utilized to minimize postoperative air leaks, including applying exogenous materials to buttress staple sutures (e.g., bovine pericardial or polytetrafluoroethylene strips), fibrin sealant to areas of air leak intraoperatively, and creating a "pleural tent."[92–95] The Brompton technique, or modified Monaldi procedure, utilizes a limited thoracotomy to visualize the bulla, insufflation of the bulla with iodized talc, and drainage of the bulla for several days with a Foley catheter under water seal.[81,96,97] Talc is subsequently instilled into the pleural cavity to achieve pleurodesis.

The postoperative approach includes careful attention to respiratory status, pain control, minimizing bronchoconstriction and hyperinflation, monitoring for development or worsening of a pneumothorax, and prevention of thromboembolic disease. Attention to the proper function of chest tubes is key to minimize the negative implications of pneumothorax. Thoracostomy tubes are generally left in place until the lung is fully expanded and there is no evidence of air leak. In those patients with persistent slow air leaks a minichest tube with a unidirectional flutter valve (e.g., Heimlich valve) can be used to facilitate discharge of the patient. The management of postoperative pain to ensure early mobilization of the patient and effective cough is crucial to minimize complications.[86]

SUMMARY

Recognition of bullous lung disease and its causes, classification, and underlying pathophysiology have important clinical implications. Careful clinical, radiographic, and physiologic assessment allows identification of patients whose dyspnea may be substantially improved through a variety of medical, surgical, and bronchoscopic interventions.

CHAPTER 51

Bronchiectasis

Gregory Tino

INTRODUCTION

Bronchiectasis is an entity characterized pathologically by airway inflammation, and permanent bronchial dilatation, and clinically by cough, sputum production, and exacerbations with recurrent respiratory tract infections. Bronchiectasis has a long history, having been first described formally by Laennec in the early 19th century.

Bronchiectasis is a heterogeneous syndrome with many different contributing etiologies. No animal model exists for bronchiectasis, and its pathogenesis remains poorly understood. It is a disease characterized by airway inflammation arising from infection in genetically susceptible individuals. Permanent damage to ciliated airway epithelium usually results from direct impact of bacterial pathogens (neutrophil recruitment via glycoproteins and IL-8, biofilm formation), as well as neutrophil-mediated host response to these pathogens. This results in direct damage to bronchial walls, epithelial cell damage, and goblet cell hyperplasia. Human neutrophil elastase (HNE), a proteolytic enzyme mainly involved in the response against bacteria, is thought to play a key role in producing tissue damage. Peter Cole described a "vicious circle" hypothesis that provides a useful conceptual framework: According to the hypothesis, neutrophilic inflammation caused by an initial insult results in airway destruction in susceptible individuals. The anatomic disruption leads to abnormal mucus clearance, setting the stage for chronic bacterial infection that then propagates the cycle of airway inflammation and bronchiectasis.[1]

Although it has been described as an orphan disease, bronchiectasis unrelated to cystic fibrosis (CF) is commonly recognized in clinical practice. Based on a large, geographically diverse health insurance claims database, the prevalence of non-CF bronchiectasis has been estimated at 52 cases/100,000, with an estimated total number of total cases greater than 110,000 in the United States.[2] A more recent study suggested a higher prevalence of 139 cases per 100,000 persons.[3]

The prevalence of bronchiectasis increases with age and appears to be more common in women (1.3- to 1.6-fold higher prevalence) and Asians (2.5- and 3.9-fold higher prevalence in Caucasians and African Americans, respectively). The prevalence has increased by 8.7% per year.[4] Similar epidemiologic findings have been reported in Europe; the incidence and point prevalence of bronchiectasis increased yearly during the period between 2004 and 2013.[5]

Bronchiectasis is also associated with significant economic cost, including that associated with an increased number of hospitalizations compared with age-matched controls. Finally, bronchiectasis is associated with a notable impairment of quality of life and mortality, likely influenced by sputum volume, severity of airflow obstruction, and the presence of chronic gram-negative infection, particularly with *Pseudomonas aeruginosa*.

DIAGNOSIS

Establishing a diagnosis of bronchiectasis requires an organized and systematic approach, with consideration of the elements of the history and physical examination, chest imaging, and laboratory data, as well as additional studies. Identifying specific underlying causes of bronchiectasis is equally important, as doing so may directly impact treatment in as many as 40% of patients.[6]

Clinical Presentation

Bronchiectasis should be suspected in individuals who report a history of persistent productive cough and sputum production, recurrent respiratory tract infections requiring antimicrobial therapy, or *Pseudomonas aeruginosa* lung infection, especially in the absence of previously identified risk factors. The diagnosis should also be suspected in never-smokers diagnosed with COPD and thought to have recurrent COPD exacerbations. Recurrent, unexplained hemoptysis may be a presenting scenario on rare occasions.[7]

Other factors to consider include (1) patient age, as genetic causes such as CF and primary ciliary dyskinesia (PCD) are more common in younger individuals; (2) extrapulmonary signs or symptoms; and (3) comorbidities that may predispose to bronchiectasis, including allergic bronchopulmonary aspergillosis (ABPA) and connective tissue disorders such as rheumatoid arthritis (RA) and Sjögren syndrome.

The clinical course of bronchiectasis is classically punctuated by exacerbations, which generally include episodes of worsening respiratory and/or systemic symptoms that require an intervention, such as antibiotics.

A proposed consensus definition for pulmonary exacerbations[8] is a person with bronchiectasis and deterioration in at least 3 of the following key symptoms for at least 48 h: (1) cough; (2) sputum volume and/or consistency; (3) sputum purulence; (4) breathlessness and/or exercise tolerance; (5) fatigue and/or malaise; (6) hemoptysis *and* clinician determination that a change in bronchiectasis treatment is required.

Chest Imaging

High-resolution computed tomography (HRCT) of the lung, which incorporates thin sections with high spatial frequency, is an indispensable diagnostic study for bronchiectasis (Figs. 51-1 to 51-5). Characteristic radiologic findings[9] include airway dilation, denoted by a luminal diameter greater than 1 to 1.5 times the adjacent vessel (*tram lines* and *signet-ring sign*, as well as absence of tapering from the central to peripheral areas of the lung) (Fig. 51-1), bronchial wall thickening, mucoid impaction, and/or cysts arising from the bronchial wall.

Other features that may be present include a "tree in bud" pattern and areas of consolidation. Although several grading systems have been proposed to correlate clinical disease severity with the extent of bronchiectasis on imaging, none has been validated in large prospective trials. The radiologic distribution of bronchiectasis can also be useful in evaluating underlying causes. The differential diagnosis of localized or focal disease is limited and includes postinfectious causes; processes causing larger airway obstruction, including bronchial strictures; endobronchial mass lesions, such as carcinoid tumors; and foreign body impaction (Fig. 51-2).

In those with multifocal or diffuse disease, the differential diagnosis is much broader and requires casting a much wider diagnostic net. Important causes include nontuberculous mycobacterial infection; congenital syndromes, such as CF (Fig. 51-3) and PCD; immunodeficiency states (e.g., common variable immunodeficiency, HIV); immune-mediated disorders (ABPA); and RA and Sjögren syndrome, among others. Table 51-1 illustrates differential diagnosis of bronchiectasis based on radiologic distribution of findings.

In addition, specific imaging findings can be highly correlated with clinical entities. For example, the presence of right middle lobe and lingular bronchiectasis with nodular changes is highly suggestive of nontuberculous mycobacterial infection (Fig. 51-4). Central bronchiectasis with mucoid impaction is characteristic of ABPA (Fig. 51-5). The diagnosis of Mounier-Kuhn syndrome can be confidently established by the finding of tracheobronchomegaly.

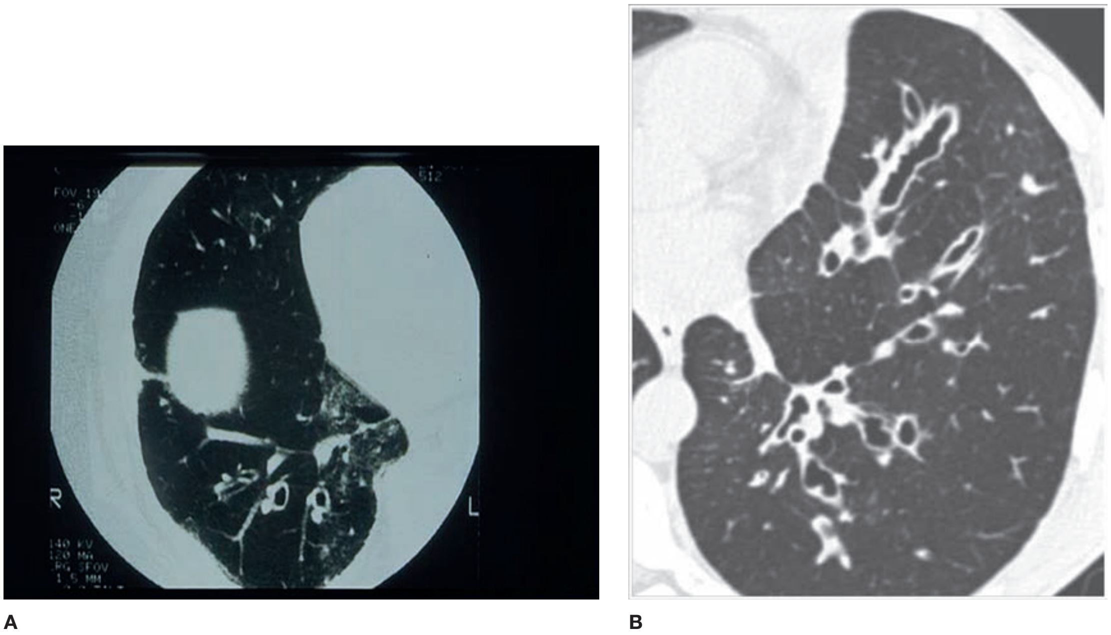

Figure 51-1 Characteristic radiologic findings of bronchiectasis: airway dilation and bronchial wall thickening. **A.** Signet-ring sign. **B.** Tram-track sign.

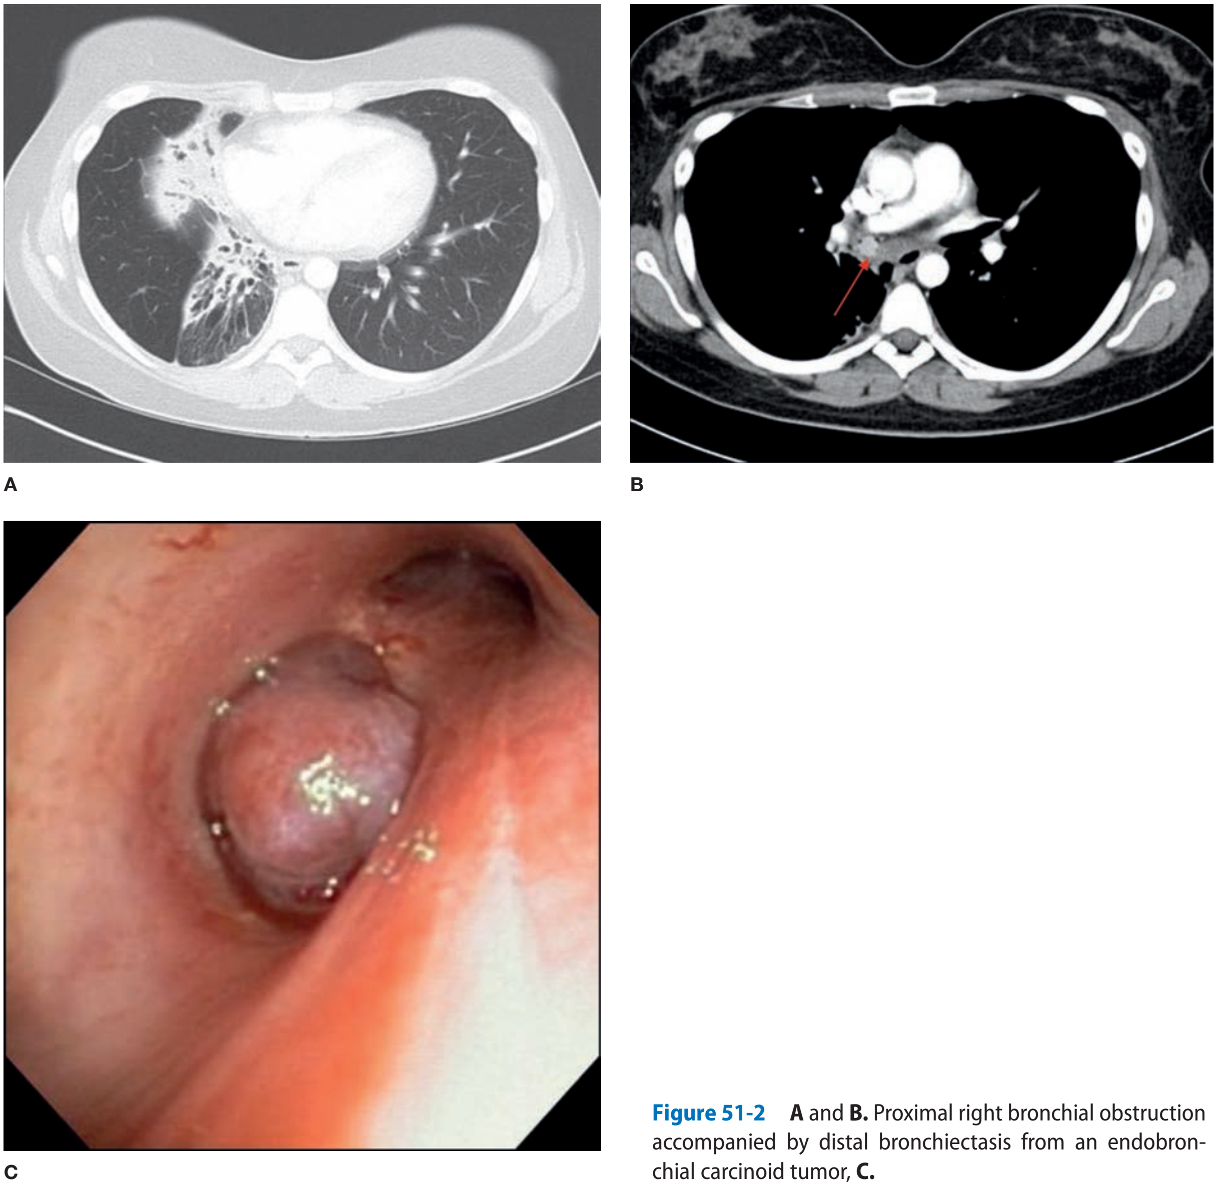

Figure 51-2 **A** and **B.** Proximal right bronchial obstruction accompanied by distal bronchiectasis from an endobronchial carcinoid tumor, **C.**

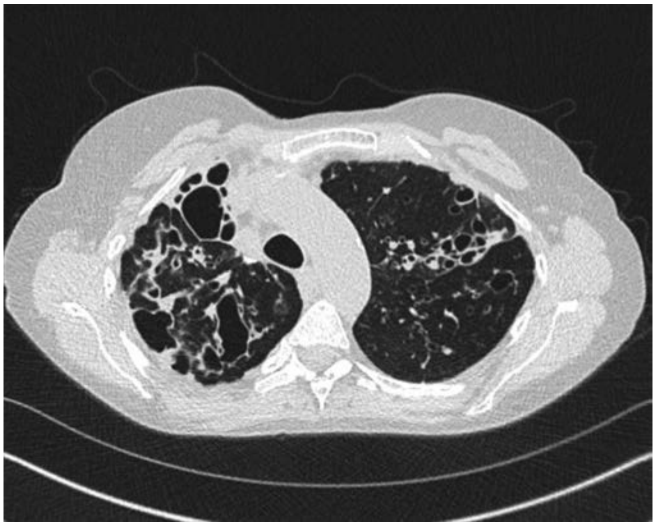

Figure 51-3 Severe upper lobe cystic bronchiectasis, consistent with cystic fibrosis.

Bilateral lower lobe bronchiectasis typically suggests possible aspiration (Fig. 51-6).

■ Laboratory Studies

Several guidelines have been published to help clinicians direct the diagnostic workup, although the recommendations are typically conditional and based on weak data. The British Thoracic Society (BTS) and European Respiratory Society (ERS) recommend a "minimum bundle" of tests that should be obtained in all patients.[10,11] These include complete blood count with differential (assessing for leukopenia, eosinophilia); serum immunoglobulins; testing for ABPA, including a serum IgE level, *Aspergillus*-specific IgE and IgG, and *Aspergillus* skin test; and routine sputum culture.

TABLE 51-1 Clinical Approach to the Patient with Suspected Bronchiectasis

History	Recurrent lower and/or upper respiratory tract infections, pneumonia Daily mucopurulent sputum production
Initial studies	CBC with differential Testing for ABPA Immunoglobulins IgG, IgM, IgA Sputum for bacterial culture
Confirms diagnosis	High-resolution chest CT scan
Other studies	Pulmonary function (spirometry pre- and postbronchodilator) Sweat chloride and/or genetic panel for CFTR alleles Connective tissue disease serologies HIV testing Sputum for AFB culture Nasal nitric oxide α_1-Antitrypsin level; phenotype Serum antibody response to bacterial antigen challenge, e.g., pneumococcal vaccine

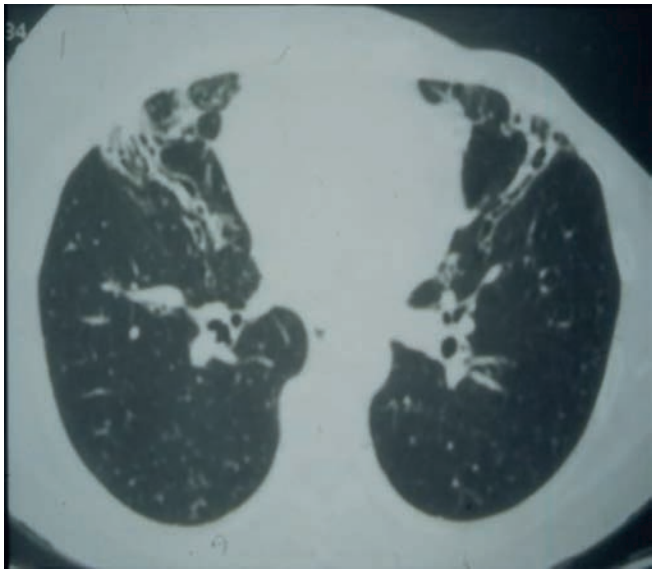

Figure 51-4 Right middle lobe and lingula bronchiectasis associated with nodular densities, highly suggestive of nontuberculous mycobacterial infection.

Additional testing should be pursued as dictated by other clinical information. Testing for CF, including both sweat chloride test and cystic fibrosis transmembrane conductance regulator (CFTR) gene mutation analysis, has been recommended for all children and all adults up to age 40 years. In those older than 40 years, CF testing should be considered in those with upper lobe bronchiectasis, persistent isolation of *Staphylococcus aureus* from the sputum, features of malabsorption, male primary infertility, history of childhood steatorrhea, and recurrent unexplained pancreatitis. The presence of dextrocardia, history of neonatal respiratory distress, chronic rhinosinusitis or otitis media, or infertility should prompt an evaluation for PCD. Table 51-1 summarizes the clinical approaches for patients with suspected bronchiectasis.

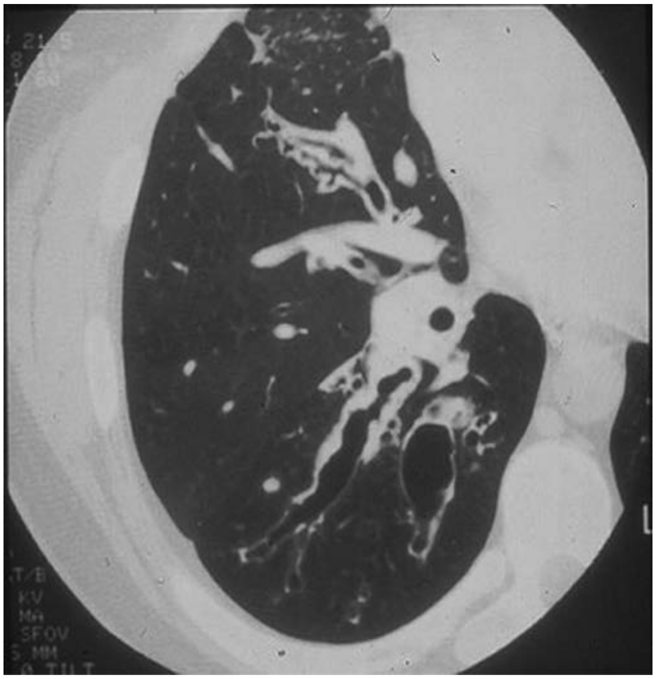

Figure 51-5 Central bronchiectasis and mucoid impaction (finger-in-glove sign), characteristic of ABPA.

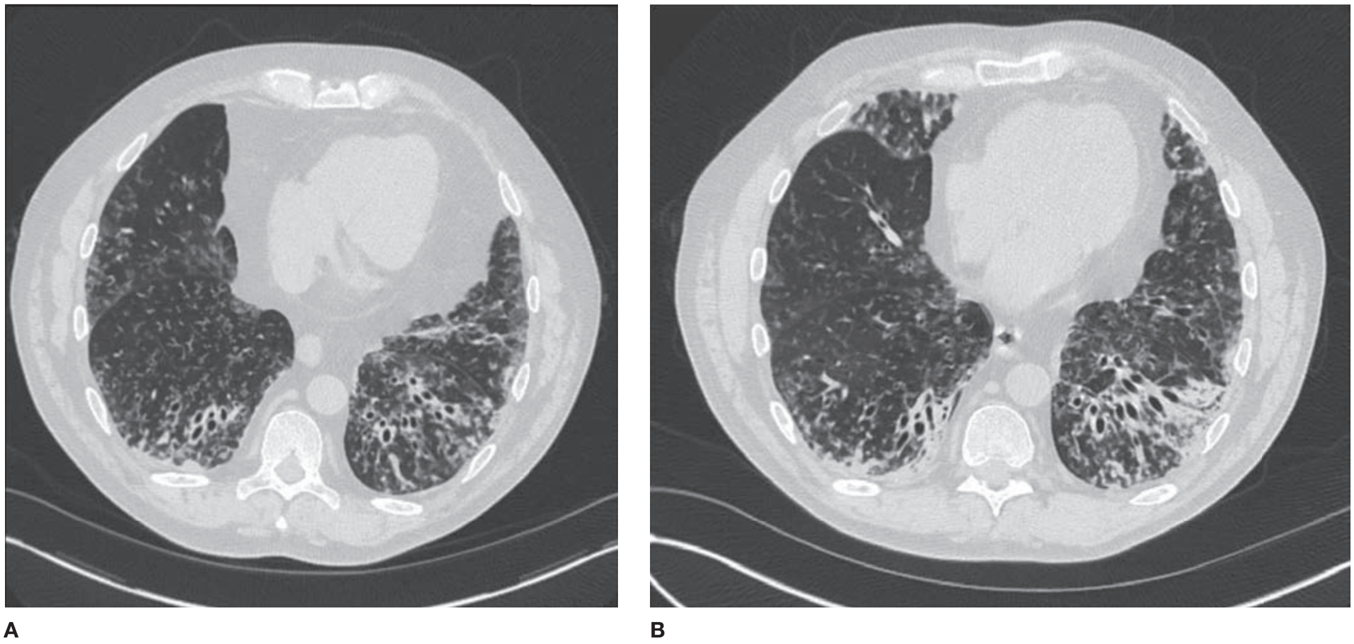

Figure 51-6 Bilateral lower lobe bronchiectasis with bronchiolitis/tree-in-bud infiltrates and consolidation, typical of GERD and acid aspiration.

PHENOTYPING

The use of clinical phenotyping has been applied to a number of lung diseases, including asthma and chronic obstructive pulmonary disease (COPD) and, more recently, to bronchiectasis. A phenotype is a physical trait that is determined by the results from a genotype. A clinical phenotype refers to the presentation of a disease in the given individual that is influenced by a number of factors. Grouping individuals on the basis of common clinical characteristics that relate to clinically meaningful outcomes, such as response to therapy and mortality, can be quite powerful and may influence endpoints for research and treatment decisions, especially in heterogeneous syndromes like bronchiectasis.

Phenotyping of bronchiectasis can be based on underlying etiology, comorbidities, or disease severity, among other considerations. However, one phenotype that has emerged is the "frequent exacerbator."[12] This phenotype was established using a database of more than 2700 subjects who were categorized by baseline exacerbation frequency. A history of frequent exacerbations, particularly 3 or more per year, was a strong predictor of future exacerbations. There was a strong relationship between a number of baseline exacerbations and the frequency in the first year of the study. Other independent predictors for frequent exacerbations include those with *Pseudomonas aeruginosa* or *Haemophilus influenzae* infection, impaired lung function (FEV_1 <50% predicted), and coexisting COPD. Importantly, frequent exacerbators exhibited worse quality of life, higher rates of hospitalization, and increased mortality.

TREATMENT

It must be stated that there are presently no approved specific therapies for bronchiectasis. In addition, available guidelines regarding management are based on low-quality evidence, and clinical trials for most of the pillars of treatment are lacking. In addition, there is significant variability in the use of treatment modalities in the United States, even at expert centers,[13] underscoring the critical need for research in this area.

Several treatment options should be considered in patients with bronchiectasis. Therapies can be grouped in several categories: (1) antimicrobials, both systemic and inhaled; (2) airway clearance measures; (3) anti-inflammatory agents; (4) surgery; and (5) treatment of underlying conditions.

Antimicrobial Therapy: Treatment of Acute Exacerbations

Antimicrobial therapy is the mainstay of treatment for exacerbations of bronchiectasis and, when possible, should be directed at identifying dominant pathogens.

The bacteriology of bronchiectasis is quite complex, but a number of studies have identified *Pseudomonas aeruginosa* and *Haemophilus influenzae* as the most common pathogens cultured. These can be isolated in as many as 35% of patients with bronchiectasis. Other important pathogens include *Staphylococcus aureus*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae*. However, an empiric antibiotic choice is often necessary as no dominant pathogen can be identified in as many as 20% to 25% of patients.

A number of factors influence the decision to start antibiotic therapy. Paramount among them is the presence of symptoms consistent with a pulmonary exacerbation, as previously described. These include cough, increased sputum volume, purulence and consistency, dyspnea, and hemoptysis, as well as systemic symptoms of fever and malaise.

Sputum analysis is critical to help guide antibiotic choice and ideally should be obtained at the time of an exacerbation. Previous microbiology and antibiotic susceptibility pattern are particularly helpful in guiding therapy, as recurrent infections often occur with the same organism. In a small trial, oral levofloxacin was reported to be as effective as ceftazidime as empiric therapy.[14] Amoxicillin is commonly recommended in those without known infection with gram-negative rods (GNR). It is important to adjust and, when possible, narrow antibiotic coverage when a specific pathogen and its susceptibility profile are available. Oral antibiotics are favored for those with mild to moderate exacerbations that do not require hospitalization. In patients with severe exacerbations, infection with resistant organisms, or poor response to oral antibiotics, intravenous antibiotics may be required.

The optimal duration of antibiotic therapy remains uncertain. A minimum of 14 days is currently recommended,[11] although longer courses may be necessary as dictated by clinical response.

In a Delphi study of clinical experts,[15] consensus was achieved for the following issues regarding antibiotic treatment of bronchiectasis: (1) 10- to 14-day duration of antibiotics for acute exacerbations; (2)

sputum volume, sputum color, and exacerbation frequency as treatment endpoints; (3) combination antibiotics should not be given for acute exacerbations treated with oral antibiotics, regardless of *Pseudomonas* colonization; (4) combination antibiotics should be used in patients with severe exacerbations with *Pseudomonas aeruginosa* or MRSA; and (5) in those individuals with a decline in FEV_1 but no changes in respiratory symptoms, antibiotics should be deferred.

Antimicrobial Therapy: Aerosolized Antibiotics

There has been great interest in the use of aerosolized antibiotics for treatment of bronchiectasis, an approach that has long been the standard care for those with CF. The goal is to reduce bacterial load, since high bacterial load (as assessed by number of colony-forming units or CFUs) is a marker of lung inflammation and has been linked to high risk of future exacerbation and hospitalization.[16] Inhaled delivery methods offer several advantages, including high concentration of drug in the airway, reduced systemic absorption, and reduced systemic toxicity. Concerns with aerosolized antibiotics include adverse airway side effects and the possible emergence of antibiotic-resistant pathogens.

Aerosolized antibiotics have been specifically directed at GNR infection, particularly *Pseudomonas aeruginosa,* which has been linked to higher mortality, high risk of hospitalization, and worse quality of life, among others.[17,18] Several agents have been studied in prospective, randomized, placebo-controlled clinical trials, including tobramycin, gentamicin, and aztreonam for inhalation solution, and colistin and ciprofloxacin in both liposomal and dry powder formulations.

Tobramycin has been the focus of several published clinical trials in treatment of acute exacerbations and as chronic maintenance therapy.[19–21] Aerosolized tobramycin has been found to have a profound microbiologic impact on *Pseudomonas aeruginosa*, without promoting emergence of resistant organisms. Improvement in symptoms, quality of life, and exacerbation frequency have been suggested, but efficacy as either maintenance therapy or in treatment of acute infectious exacerbations has not been conclusively established. Associated adverse effects, including cough dyspnea and chest tightness, are well described.

Aerosolized gentamicin was studied in a randomized, year-long, placebo-controlled trial of 65 patients, 57 of whom completed the study. Findings included a 31% eradication of *Pseudomonas* and 92.8% of other pathogens in the treatment group. No *Pseudomonas* isolates developed gentamicin resistance. Treated patients were noted to have statistically significant less purulent sputum, increased time to first exacerbation, fewer exacerbations, and improved Leicester Cough Questionnaire (LCQ) and St. George Respiratory Questionnaire (SGRQ). There were no differences in 24-h sputum volume or spirometry.[22]

Two randomized, double-blind, placebo-controlled, phase 3 clinical trials of aerosolized aztreonam did not demonstrate clinical benefit; treatment-emergent adverse events, including dyspnea, cough, and increased sputum were common.[23]

More recently, inhaled colistin was evaluated in the UK in 144 patients with bronchiectasis and *Pseudomonas* infection.[24] Participants were enrolled within 21 days of acute exacerbation and received inhaled colistin or placebo daily for up to 6 months. Fewer than 10% of patients were on macrolides. The primary endpoint, time to exacerbation, was not met in the intention-to-treat (ITT) group. However, for patients adherent to more than 80% of doses, the median time to exacerbation was statistically significantly increased to 168 days in the colistin group from 103 days in the placebo group. The reported exacerbation rate was 50% in the colistin group and 72% in the placebo group. An international clinical trial is currently underway.

Trials of liposomal ciprofloxacin (ORBIT 3,4) and dry powder ciprofloxacin (RESPIRE 1,2) have been completed. Exacerbation reduction was significantly reduced in RESPIRE 1 and ORBIT 4 but not duplicated in their parallel trials.[25–27]

In summary, use of aerosolized antibiotics in treatment of acute exacerbations of non-CF-related bronchiectasis remains controversial. Aerosolized antibiotics appear to have a clear microbiologic impact, but their clinical efficacy has not yet been conclusively proven, and none is currently approved by regulatory agencies. Importantly, the emergence of clinically relevant resistant pathogens has not been yet observed. Meta-analyses have reported that aerosolized antibiotics are generally safe and better than placebo in reducing bacterial load.[28] A number of professional societies, including the European Respiratory Society, the British Thoracic Society, and the Thoracic Society of Australia and New Zealand have suggested that long-term nebulized antibiotics should be considered for those individuals with chronic *Pseudomonas aeruginosa* infection, those experiencing frequent exacerbations (>3/year), and when other therapies have been optimized.

Unanswered questions on the use of aerosolized antibiotics include administration schedule (daily versus cycling, e.g., 28 days off/on) and their role in comparison with chronic macrolide therapy.

Airway Clearance Techniques

Airway clearance techniques (ACT) are those designed to enhance mucociliary clearance. The goals of ACT are to improve symptoms, reduce exacerbation frequency, and improve quality of life. There are a number of modalities, both mechanical and pharmacologic, used in clinical practice. ACT are safe, but there is little strong evidence to establish their efficacy. However, published guidelines have recommended the use of ACT, particularly for individuals with chronic productive cough or those who have difficulty expectorating sputum.[7,11]

Mechanical Modalities

Mechanical modalities to facilitate airway clearance include positive expiratory pressure devices and high-frequency oscillation modalities.

Use of *positive expiratory pressure (PEP)* devices is based on generation of positive expiratory pressure when an individual exhales against fixed resistance, thereby preventing airway closure and promoting mobilization of airway secretions. Several PEP devices are available, including Acapella, Aerobika, and Flutter. These devices are the most commonly utilized ACTs in the United States, as reported by the U.S. Bronchiectasis Registry.[29] A small, randomized, 3-month crossover trial of the Acapella device reported an improvement in total LCQ, increased 24-h sputum volume, and improved exercise capacity. No change in spirometry or sputum microbiology were reported.[30] Additional studies are necessary to establish the benefit of PEP devices.[31]

With high-frequency chest wall oscillation, external chest oscillations are applied to the chest using a fitted vest. Once again, convincing data on efficacy, both short- and long-term, are lacking; however, enhanced sputum expectoration and quality of life, and a decrease in hospitalization for exacerbations have been suggested.[32,33]

Pharmacologic Agents

A variety of pharmacologic approaches have been employed in facilitating airway clearance. The most common are considered below.

Hyperosmolar agents, including inhaled mannitol and hypertonic saline, are commonly used agents. A phase 3, multicenter, randomized, controlled, double-blind clinical trial of inhaled mannitol in 485 patients did not reveal a statistically significant reduction in the rate of acute exacerbations. There were statistically significant improvements in time-to-first exacerbation and QOL. Therapy was well tolerated.[34]

Use of hypertonic saline is part of standard care for CF and has been demonstrated to reduce the frequency of pulmonary exacerbations and, perhaps, improve quality of life. It is available in 3% and 7% formulations. Small clinical studies in bronchiectasis suggest a decrease in sputum viscosity and a decrement in disease exacerbations, but more definitive data are lacking. Reported associated adverse effects include throat irritation, salty taste, and dyspnea.

Use of bronchodilator agents, such as albuterol, have generally not been found to enhance bronchopulmonary hygiene.

Although use of recombinant human deoxyribonuclease (rhDNase) has been shown to be efficacious in individuals with cystic fibrosis, in a large clinical trial, pulmonary exacerbations were found to be more frequent and decline in FEV_1 greater in patients with non-CF bronchiectasis who received rhDNase.[35] Therefore, the agent should not be used routinely in bronchiectasis. This underscores the principle that extrapolation of data on treatment for patients with cystic fibrosis to those without cystic fibrosis be done cautiously.

In summary, ACT should be considered in symptomatic patients, in those who have chest congestion and difficulty expectorating sputum, and, perhaps, in those with frequent exacerbations. In the absence of data, the modality chosen should be one that maximizes patient adherence and minimizes expense.

■ Anti-inflammatory Therapy

Anti-inflammatory therapy for bronchiectasis includes macrolides and other pharmacologic agents.

Macrolide Antibiotics

Macrolide antibiotics have been a focus of study because of their myriad anti-inflammatory and immunomodulatory properties. Among other effects, macrolides inhibit mucus hypersecretion, reduce IL-8 and neutrophil elastase, inhibit neutrophil adhesion to epithelial cells, reduce biofilm formation, and inhibit production of reactive oxygen species from neutrophils. Macrolides have been used successfully in other airways diseases, including cystic fibrosis, diffuse panbronchiolitis, posttransplant obliterative bronchiolitis, and COPD. Older small studies in bronchiectasis suggested a reduction in sputum volume and exacerbation frequency with use of macrolides. The reduction of exacerbations is a particularly desirable clinical endpoint, given their adverse impact on quality of life. In addition, reducing exacerbations may also decrease hospitalizations and overall cost of care.

To date, three published clinical trials have evaluated the efficacy of macrolides in bronchiectasis. Although there were differences in methodology and agents used, all three reported significant decrements in exacerbation frequency.

The EMBRACE trial[35] was carried out at three centers in New Zealand. A total of 141 patients who had at least one exacerbation in the prior year were treated with thrice-weekly azithromycin versus placebo for 6 months. Those receiving azithromycin were found to have a 62% reduction in the rate of acute exacerbations at both 6 and 12 months, as well as increased time to first exacerbation. There were no significant differences in FEV_1, SGRQ, or 6-min walk test distance.

The BAT trial[36] from the Netherlands included patients who had experienced at least three exacerbations in the previous year. A total of 83 patients were treated with azithromycin 250 mg daily or placebo for 12 months. An absolute risk reduction of 33.5% was demonstrated in those taking azithromycin. A 1.03% increase in FEV_1 per 3 months versus a decrement of 0.1% in the placebo group also was noted.

The BLESS trial,[37] the largest of the three trials, was conducted in Australia. Of 679 screened patients, 107 completed a double-blind, placebo-controlled, single-center trial. Enrolled individuals had at least 2 exacerbations in the preceding 12 months and were treated with erythromycin, 40 mg twice daily, for 48 weeks (with a 4-week washout) versus placebo. A significant reduction in the rate of protocol-defined pulmonary exacerbations from 1.97 in the placebo group to 1.29 in the treatment group was reported. In addition, a reduction in 24-h sputum production and a 2.2% attenuation in the rate of FEV_1 decline were noted.

At present, macrolide therapy may be targeted specifically to those patients with frequent exacerbations (>3/year), normal ECG, and no significant underlying cardiac disease. Macrolides should be avoided in patients with known or strongly suspected nontuberculous mycobacterial infection in whom macrolide monotherapy is the main risk factor for development of macrolide resistance, which is associated with a poorer prognosis, including increased mortality. The optimal duration of treatment has not yet been established.

Little published data are available to guide a decision on when to use inhaled antibiotics versus long-term macrolide treatment. The 2017 ERS guidelines suggest that inhaled antibiotics be used in patients with chronic *Pseudomonas* infection and ≥3 exacerbations per year. Macrolides can be used in those with frequent exacerbations with non-*Pseudomonas* pathogens or those who exhibit intolerance or lack of efficacy with inhaled antibiotics. Combined therapy with a macrolide and inhaled antibiotics may be considered when there is a suboptimal response to either agent alone.[11]

Use of macrolide antibiotics in bronchiectasis is certainly not without other concerns. These include commonly reported adverse gastrointestinal symptoms, ototoxicity, and possible development of bacterial antibiotic resistance. In addition, a small risk of a sudden cardiac event, particularly in those at highest risk for cardiovascular disease.[38]

Other Pharmacologic Therapies

Brensocatib, an oral, reversible inhibitor of dipeptidyl peptidase 1 (DPP1), an enzyme responsible for activating neutrophil serine proteases (NSPs, such as neutrophil elastase), was recently reported to be well tolerated and associated with a significant reduction in the rate of exacerbation and significantly prolonged time to first exacerbation over 24 weeks versus placebo.[39] An international phase 3 trial is currently underway.

A rotating antibiotic strategy was commonly employed by clinicians in the past. In general, there is no evidence to support the use of systemic, nonmacrolide, suppressive, or maintenance therapy.

Inhaled or chronic systemic corticosteroids should not be used routinely in bronchiectasis unless indicated for other comorbidities, such as asthma or COPD.[11] There have been reports of an increased risk of nontuberculous mycobacterial infection associated with inhaled corticosteroid therapy.[40]

Specific therapy should obviously be used in patients with significant underlying disorders. Examples include immunoglobulin replacement for CVID, systemic corticosteroids and antifungal agents for ABPA, α_1-antitrypsin augmentation therapy in α_1-antitrypsin deficiency, and guideline-based antibiotics for nontuberculous mycobacterial infection.

■ Surgery

No robust prospective data are available comparing surgical resection to medical therapy for individuals with bronchiectasis. A number of retrospective case series have, however, demonstrated that surgery for selected patients can be accomplished with acceptable morbidity and mortality.[41,42] Surgery is an option to be considered for those with massive hemoptysis refractory to other measures, such as bronchial artery embolization; those with localized bronchiectasis who have frequent exacerbations despite medical therapy; and as an adjunct to antibiotics for patients with nontuberculous mycobacterial infection.[11,43]

Supportive Measures

Important supportive measures for bronchiectasis include appropriate vaccination, supplemental oxygen for associated hypoxemia, and pulmonary rehabilitation therapy for those with functional impairment. Short courses of systemic corticosteroids for bronchospasm associated with some exacerbations may be warranted. Finally, lung transplantation can be successfully utilized in patients with advanced disease.

NATURAL HISTORY AND PROGNOSIS

The natural history and prognosis of bronchiectasis are not well described. A study of 91 patients in the United Kingdom followed consecutively over 13 years starting in the mid-1990s demonstrated a mortality rate of 29.7%.[44] This was higher than the expected death rate for males and females of 14.7% and 8.9%, respectively, in an age-matched cohort. Of note, respiratory causes accounted for about 70% of all deaths. Predictors of mortality in this study included older age, history of *Pseudomonas aeruginosa* infection, impaired lung function, and poor quality of life.

A number of clinical prediction tools for bronchiectasis have been developed. The Bronchiectasis Severity Index (BSI) has recently been derived and validated in large cohorts as a tool for disease severity.[45] The BSI is comprised of nine parameters including age, BMI, FEV_1, hospital admissions, exacerbations, MRC dyspnea scores, *Pseudomonas aeruginosa* colonization, colonization with other organisms, and radiologic severity. Higher BSI scores are associated with higher mortality, more frequent hospital admissions, and poor quality of life as assessed by SGRQ.

Independent predictors of mortality in bronchiectasis include older age, FEV_1 <30% predicted, lower BMI, prior hospitalizations, and ≥3 exacerbations in the previous year. Independent predictors of hospitalization include prior admissions, MRC dyspnea score >4, FEV_1 <30% predicted, *Pseudomonas aeruginosa* colonization, and multifocal bronchiectasis with ≥3 lobes involved on HRCT.

The FACED Score, derived from an observational study in Spain, classifies severity according to prognosis.[46] It focuses on five variables, including chronic *Pseudomonas aeruginosa* infection, mMRC score, FEV_1, age, and number of affected lobes. The score has been validated to predict all-cause mortality.

SUMMARY AND FUTURE DIRECTIONS

In summary, bronchiectasis is a heterogeneous clinical entity that is more common and clinically impactful than previously thought. Recurrent respiratory infections and impairment of quality of life are its clinical hallmarks. Prompt and accurate diagnosis requires vigilance for suggestive clinical signs and symptoms and initiation of objective studies. Treatment is multifaceted and includes both specific and supportive measures, many of which have limited evidence-based support. Despite progress, much work lies ahead to expand basic knowledge of the pathophysiology of bronchiectasis and potential novel treatment options.

CHAPTER 52

Interstitial Lung Disease: A Clinical Overview and General Approach

Aditi Mathur
Danielle E. Antin-Ozerkis

INTRODUCTION

Interstitial lung disease (ILD) refers to a heterogenous collection of lung disorders that are grouped together because they share clinical, radiographic, and pathologic features. ILD is also referred to as *diffuse parenchymal lung disease (DPLD)* to clarify that the interstitium is not the only compartment of the lung affected. For example, organizing pneumonia and pulmonary alveolar proteinosis are alveolar filling processes, whereas respiratory bronchiolitis and chronic hypersensitivity pneumonitis may center on the airway. Occasionally, purely airway-centered disease like bronchiolitis obliterans may be initially identified as an ILD because of overlapping radiographic features. A structured approach is necessary since prognosis and therapy vary considerably depending on the diagnosis. While many ILDs are extremely rare, there are some, such as idiopathic pulmonary fibrosis (IPF) and sarcoidosis, that are seen commonly in general pulmonary practice.

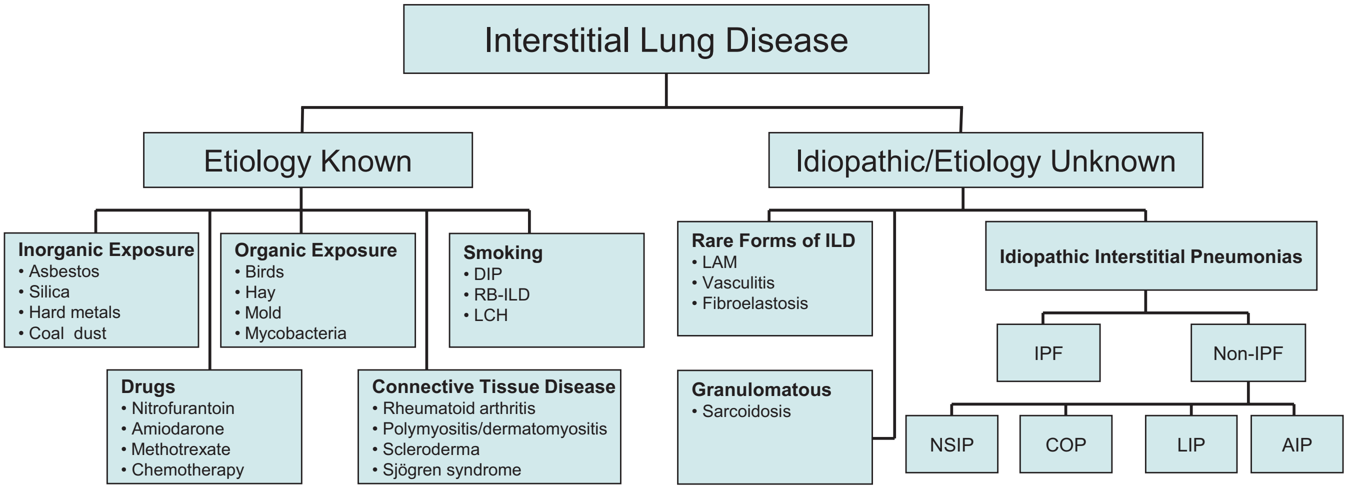
ILD frequently presents with dyspnea on exertion, diffuse bilateral infiltrates on chest imaging, and restriction with diffusion impairment on physiologic testing. When tissue is obtained, the lung parenchyma may contain any combination of inflammation and fibrosis. Masqueraders of ILD, such as infection, pulmonary edema, and malignancy, will be encountered in the assessment of abnormal chest imaging. Distinguishing these from true ILD is essential.

Specific diagnosis is based upon a comprehensive history and careful physical examination, as well as review of laboratory data, physiologic studies, radiography, and, in some cases, pathologic tissue obtained from lung biopsy. Multidisciplinary review is an important part of the process and can have a significant impact on diagnostic and management decisions. For each patient, decisions regarding diagnostic approach and therapy must be individualized based upon the patient's own personal approach to medical care, in combination with their respiratory status and comorbid medical conditions.

GENERAL APPROACH TO ILD

Several proposed classification schemes for ILD include radiographic, histopathologic, and clinical characteristics.[1] The American Thoracic Society (ATS)/European Respiratory Society (ERS) consensus panel classification system on the idiopathic interstitial pneumonias was published in 2002 and was updated in 2013 and 2018 with a focus on the diagnosis of IPF.[2–4] Additional guidelines on the diagnosis of hypersensitivity pneumonitis and sarcoidosis have further added to the diagnostic armamentarium.[5,6]

Despite the availability of such guidelines, in the care of any individual patient, it is useful for the clinician to have a methodical diagnostic approach. This process should incorporate a combination of historic, clinical, radiographic, and, when indicated, pathologic features. Distinguishing those patients who have a known cause for their ILD (e.g., connective tissue disease, occupational or environmental exposure, or drug toxicity) from those who do not (e.g., IPF, sarcoidosis) is one helpful diagnostic categorization (Fig. 52-1). Clinical features, such as acuity of onset and specific patient characteristics, may also help to classify disease (Table 52-1). For example, the subacute time course of symptom development in a patient with organizing pneumonia will be quite different than the insidious onset of dyspnea in IPF. Radiographic patterns often guide the clinician toward a specific diagnosis. For example, patients with IPF will have CT findings of basilar traction bronchiectasis and honeycombing, while those with sarcoidosis may demonstrate upper lobe–predominant nodular opacities with retraction and volume loss. Histopathologic characterization may range from acute inflammation to granulomatous involvement, to fixed fibrosis and collagen deposition. Pathologic pattern may be the specific feature that clarifies the ILD diagnosis.



Interstitial Lung Disease
Etiology Known
Idiopathic/Etiology Unknown
Inorganic Exposure
• Asbestos
• Silica
• Hard metals
• Coal dust
Organic Exposure
• Birds
• Hay
• Mold
• Mycobacteria
Smoking
• DIP
• RB-ILD
• LCH
Drugs
• Nitrofurantoin
• Amiodarone
• Methotrexate
• Chemotherapy
Connective Tissue Disease
• Rheumatoid arthritis
• Polymyositis/dermatomyositis
• Scleroderma
• Sjögren syndrome
Rare Forms of ILD
• LAM
• Vasculitis
• Fibroelastosis
Granulomatous
• Sarcoidosis
Idiopathic Interstitial Pneumonias
IPF
Non-IPF
NSIP
COP
LIP
AIP

Figure 52-1 An overview of ILD classification. AIP, acute interstitial pneumonia; COP, cryptogenic organizing pneumonia; DIP, desquamative interstitial pneumonia; IPF, idiopathic pulmonary fibrosis; LAM, lymphangioleiomyomatosis; LCH, Langerhans cell histiocytosis; LIP, lymphocytic interstitial pneumonia; NSIP, nonspecific interstitial pneumonia; PPFE, pleuroparenchymal fibroelastosis; RB-ILD, respiratory bronchiolitis interstitial lung disease. *(Data from ATS/ERS classification, 2018.)*

TABLE 52-1 Time Course of Disease Onset

Acute
Cryptogenic organizing pneumonia
Acute eosinophilic pneumonia
Acute hypersensitivity pneumonitis
Diffuse alveolar hemorrhage
Acute interstitial pneumonia
Acute exacerbation of idiopathic pulmonary fibrosis
Subacute to Chronic
Connective tissue disease–associated ILD
Idiopathic pulmonary fibrosis
Sarcoidosis
Chronic hypersensitivity pneumonitis
Occupational lung disease
Nonspecific interstitial pneumonia
Desquamative interstitial pneumonia
Respiratory bronchiolitis interstitial lung disease
Lymphocytic interstitial pneumonia
Chronic eosinophilic pneumonia
Pleuroparenchymal fibroelastosis
Combined pulmonary fibrosis and emphysema

It is important to note that the names used to describe the clinical entities themselves must be distinguished from the radiographic and pathologic terms used to describe the findings. For example, IPF is the clinical entity associated with a usual interstitial pneumonia (UIP) pattern on chest CT and histopathology. However, the finding of a UIP pattern alone does not ensure a diagnosis of IPF, as this pattern may also be seen in other entities, including connective tissue disease and hypersensitivity pneumonitis.

CLINICAL HISTORY

Below we consider important patient characteristics, as well as respiratory and nonrespiratory presentations of ILD.

Patient Characteristics

Age and gender are key characteristics to consider. Certain forms of ILD are more common in particular age groups. IPF is a disease more common in the older population, whereas connective tissue disease–associated ILD, sarcoidosis, lymphangioleiomyomatosis (LAM), and hereditary forms of ILD are typically diagnosed at a younger age. CTD-ILD is more common in women, and LAM is almost exclusively diagnosed in women during childbearing years. A diagnosis of IPF in a 30-year-old woman, for example, should be strongly reconsidered.

Respiratory Presentation

The typical presentation of ILD is nonspecific and may include vague pulmonary complaints, such as dyspnea on exertion or cough. In some cases, the time course of the disease may suggest certain forms of ILD (Table 52-1). The acute forms of ILD must be distinguished from respiratory infections and pulmonary edema due to congestive heart failure.

Other clinical features may affect the presentation as well. In elderly or disabled patients, musculoskeletal issues may limit mobility and dyspnea may be a late symptom. In a patient with significant cardiac disease, relatively mild ILD may cause an earlier onset of disabling dyspnea and the discovery of ILD for this reason. It is helpful to attempt an objective quantification of the degree of dyspnea, such as the distance the patient walks before becoming breathless or the number of steps climbed before a rest must be taken.

Often a persistent cough after a respiratory infection leads to the initial chest radiograph. While other respiratory symptoms are less common, they may help focus the differential diagnosis. For example, a history of wheezing may suggest an airway-centered process such as hypersensitivity pneumonitis, eosinophilic pneumonia, or sarcoidosis. Substernal chest pain is commonly described by patients with sarcoidosis. Pleuritic chest pain may herald serositis in a patient with connective tissue disease, or pneumothorax in cystic lung diseases, such as lymphangioleiomyomatosis (LAM) (Chapter 60) and Langerhans cell histiocytosis (LCH) (Chapter 59).[7–9] Hemoptysis may suggest diffuse alveolar hemorrhage, although it is not present in most cases.[10]

Systemic Symptoms

Connective tissue disease is a frequent cause of ILD, and some patients may come for pulmonary evaluation with a pre-existing diagnosis. However, most will not, and it is incumbent on the clinician to search carefully for suggestive symptoms and signs of underlying autoimmune disease; the pulmonologist may be the first to make such a diagnosis, prompted by the presence of ILD. In some cases, nonspecific symptoms such as night sweats, fever, fatigue, or weight loss suggest an underlying inflammatory condition. In others, the clinician can arrive at a specific diagnosis by performing a thorough review of systems. Careful questioning regarding skin rash and other dermatologic symptoms may lead to the discovery of dermatomyositis as demonstrated by a heliotrope rash, Gottron's papules, or "mechanic's hands," all of which are relatively specific features of this disease. Patients with underlying systemic sclerosis (scleroderma) may give a history of skin tightness and thickening, telangiectasias, Raynaud's phenomenon, or digital pitting. Papular eruptions, lupus pernio, and erythema nodosum are sometimes seen in sarcoidosis.[11] Patients with systemic lupus erythematosus (SLE) may describe malar rash, photosensitivity skin reaction, or hair loss.

Gastrointestinal symptoms may be indicative of underlying esophageal dysmotility related to connective tissue diseases, such as systemic sclerosis, mixed connective tissue disease, and polymyositis, or may be the root cause of the ILD itself. In particular, symptoms suggestive of acid reflux (chest burning or pressure, cough after meals, regurgitation of food) should be sought. Chronic, intermittent aspiration can lead to progressive fibrotic lung disease from recurrent lung injury. Patient descriptions of coughing or choking while eating or noting food "going down the wrong pipe" are suggestive of frank aspiration and could lead to a discovery of progressive neuromuscular diseases, such as amyotrophic lateral sclerosis (ALS), prior cerebrovascular accident, or other causes of oropharyngeal and laryngeal dysfunction.[12] Lower gastrointestinal complaints, such as bloating and diarrhea, may suggest inflammatory bowel disease, which is associated with ILD,[13] or bacterial overgrowth due to bowel dysmotility in systemic sclerosis.

Musculoskeletal complaints also can be helpful in identifying underlying connective tissue disease. In particular, arthralgias, morning stiffness, joint swelling and erythema, and digital deformities may be evidence of rheumatoid arthritis, Sjögren syndrome, or mixed connective tissue disease. Swollen fingers ("sausage digits") may be observed in systemic sclerosis and polymyositis. Raynaud's phenomenon manifests as either blue/purple discoloration or whiteness of the digits (fingers or toes) in the cold.[14] In some cases, this may be quite profound and can be associated with digital ulceration and, rarely, digital gangrene. Raynaud's phenomenon is most commonly seen in scleroderma, mixed connective tissue disease, SLE, and antisynthetase syndrome.[15]

Ophthalmologic symptoms may direct the clinician toward particular clinical entities. Inquiries regarding dry eyes or the use of eye drops may uncover sicca syndrome, as seen in Sjögren syndrome, and overlap connective tissue diseases. Patients with a history of uveitis may have underlying SLE, vasculitis, or sarcoidosis.[16] Neurologic symptoms may suggest vasculitis or sarcoidosis.

The cardiac history may uncover sequelae of longstanding ILD. Increasing edema, syncopal events, or exertional chest discomfort may indicate severe pulmonary hypertension and cor pulmonale in the patient with advanced fibrotic lung disease and hypoxemia. Alternatively, in a patient with systemic sclerosis, these findings might indicate a second related but independent problem such as pulmonary arterial hypertension. The presence of palpitations or syncope in a patient with sarcoidosis can lead to a diagnosis of cardiac sarcoidosis.

The review of systems will sometimes lead to other important diagnoses. For example, more typical causes of chest discomfort with activity, such as cardiac ischemia, may be exacerbated by exertional hypoxemia. This is particularly important to remember, as patients with underlying immune-related diseases appear to be at increased risk for coronary artery disease.[17] In addition, pleuritic chest pain, leg swelling, and increasing dyspnea should prompt consideration of acute pulmonary embolism, as patients with ILD are at increased risk for this complication.[18–20]

PAST MEDICAL HISTORY

In addition to underlying connective tissue disease (systemic sclerosis, rheumatoid arthritis, dermatomyositis/polymyositis, SLE) and inflammatory bowel disease, other systemic disorders may lead to ILD or its mimics and will affect the approach to diagnosis. For example, the differential diagnosis for dyspnea and diffuse infiltrates on chest radiograph will vary markedly between immunocompetent patients and those who have undergone organ or bone marrow transplantation, are neutropenic from recent chemotherapy, or who have advanced HIV disease. In HIV disease, lymphocytic interstitial pneumonia (LIP) may be evident and may be associated with viral replication or immune dysregulation.[21] A history of acute or chronic kidney disease might suggest underlying vasculitis, pulmonary–renal syndromes, or connective tissue disease. Lysosomal storage disorders such as Niemann Pick[13] and Gaucher disease are a rare cause of ILD.[22] A history of liver disease could suggest sarcoidosis, primary biliary cirrhosis, or underlying genetic abnormalities resulting in short telomere length.[23–25] A history of facial nerve palsy (Bell's palsy) might represent unrecognized sarcoidosis.[26] As the clinician considers a patient's medical history, specific diagnoses may lead to a focused review of drugs used to treat these disorders since many are common culprits in the development of ILD (see "Medication History," below). For example, when a patient with inflammatory bowel disease presents with ILD, a history of recent sulfasalazine, mesalamine, methotrexate, or anti-TNF therapy should be sought.[13]

OCCUPATIONAL HISTORY

The occupational history should be thorough, including a review of all jobs held in the past. In particular, attention should be paid to any occupation in which a history of exposure to organic or inorganic products was present (Table 52-2).[27,28] Specific inquiries may be made regarding a history of construction work, including demolition, plumbing, and electrical work. The patient should be questioned about employment in factories and manufacturing plants, the electronics industry, metal working, stone cutting, and mining. The clinician should specifically inquire about exposure to asbestos, silica, hard metals, and beryllium, as workers often know when these have been present in their work environment.[29,30] Inquiries may additionally be made regarding the jobs held by household contacts of patients. For example, spouses may have been subjected to significant levels of dust inhalation via clothing worn by the worker.[31] In cases where a relevant exposure has occurred, details should be obtained regarding the worker's specific duties, the typical proximity to the exposure of interest, and any use of respiratory protection. In some cases, related respiratory illnesses in coworkers can raise suspicion.

TABLE 52-2 Occupational Interstitial Lung Disease

Occupation	Type of ILD	Exposure
Electrician Plumber Pipe fitter Construction worker Ship builder Insulation installer	Asbestosis	Asbestos
Stone cutter Miner Sand blaster Engineered stone countertop production worker	Silicosis	Crystalline silica dust
Metal grinder	Giant cell interstitial pneumonia Hard metal lung disease	Hard metals Cobalt Tungsten carbide
Metal worker Factory workers Nuclear weapons Aircrafts Electronics Ceramics Golf clubs Bicycle frames	Berylliosis	Beryllium
Coal worker	Coal worker's pneumoconiosis	Coal dust
Paint sprayer Plastic worker	Chemical worker's lung	Isocyanates
Bird breeder	Bird breeder's lung	Bird droppings Bird feathers
Farm worker Haying Mushroom compost	Farmer's lung Mushroom worker's lung	Thermophilic bacteria
Office worker	Humidifier lung Ventilation pneumonitis	Fungi/molds
Lifeguard	"Hot tub" hypersensitivity pneumonitis	Mycobacteria

There may be a long latency period between the exposure and the onset of symptoms and radiographic changes, so the occupational history must explore jobs held many years in the past.

A history of farm work or other agricultural employment should raise suspicion for an environmental cause of ILD. Exposure to moldy hay, bird feathers and droppings, and a variety of organic products can lead to chronic hypersensitivity pneumonitis.[32,33] There are several available questionnaires to screen for such exposures, but none have been validated. In recent ATS guidelines on hypersensitivity pneumonitis, it was recommended that the clinician might utilize their own questionnaire but that a future universal approach should be addressed in the ILD community.[5]

ENVIRONMENTAL HISTORY

Organic exposures are also frequently encountered in household and office settings.[27] For example, humidification systems may be contaminated with mold.[34] Hot tubs and other aerosolized water sources have led to lung disease related to growth of *Mycobacterium avium*.[35] The exposure history should include a thorough inquiry regarding the home heating and humidification system, a history of water damage, or visible evidence of significant mold growth. An assessment of the timing of any water damage relative to the onset of the lung disease can be helpful. Domestic birds are a common source of feathers and dropping antigen. Bird owners often have multiple birds and have owned birds for many years. Frequently, these pets are considered cherished members of the family, residing in bedrooms and main living spaces. A history of hobbies and materials used should also be obtained. No occupation or recreational activity should be ignored. For example, even wind instruments have been linked with contamination by fungi and bacteria leading to lung disease.[36]

Cigarette smoke is one of the most common environmental exposures and is strongly linked with several forms of ILD, including desquamative interstitial pneumonia (DIP), respiratory bronchiolitis-ILD, and LCH. Cigarette smoking has been identified as a risk factor for IPF. In recent years, the use of electronic cigarettes has led to significant respiratory illness, also known as vaping product use–associated lung injury (EVALI),[37] discussed in detail in Chapter 41. It is thought that microparticles and volatile chemicals, as well as cutting agents such as vitamin E acetate, are responsible for the lung injury.[38]

MEDICATION HISTORY

Numerous drugs have been implicated in the development of ILD, ranging from acute pneumonitis to chronic fibrotic lung disease (Table 52-3), as further discussed in Chapters 64 and 65. It is important to specifically review the medication list and to particularly seek out a history of prolonged use of commonly prescribed drugs. Nitrofurantoin, used for suppression of recurrent urinary tract infections, may lead to severe ILD.[39] Amiodarone, used for management of atrial and ventricular arrhythmias, is known to lead to lung toxicity.[40] Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used and may lead to eosinophilic and other inflammatory lung disease.[41,42] While less frequently used in the general population, a history of recent chemotherapy should trigger suspicion for drug-related lung disease.[43] Similarly, a history of immune-modulating drug use, such as in the treatment of rheumatoid arthritis or Crohn's disease, may be of concern.[39,40,44,45] Immunotherapy has become standard of care in oncology, which has produced an awareness of immune-mediated adverse events, including lung toxicity (Chapter 64).

Since numerous drugs are associated with ILD, a thorough past and present medication history should be obtained for all patients with newly diagnosed ILD. A helpful online source of information is *www.pneumotox.com*. This independent resource is compiled and regularly updated by members of the University Hospital in Dijon, France, and the GEPPI (Groupe d'Etudes de la Pathologie Pulmonaire Iatrogene). It lists all reports of suspected drug-induced lung disease, categorizes the radiographic patterns observed, and gives an assessment of the quality of the compiled information.

TABLE 52-3 Drugs Commonly Implicated in Interstitial Lung Disease

Antibiotics
- Nitrofurantoin
- Minocycline
- Cephalosporins

Antiarrhythmic
- Amiodarone
- Tocainide

Anti-inflammatory
- Azathioprine
- Etanercept
- Gold salts
- Infliximab
- Methotrexate
- NSAIDs
- Penicillamine
- Sulfasalazine

Neurologic/Psychiatric
- Carbamazepine
- Phenytoin

Drugs of Abuse
- Cocaine
- Heroin
- Talc

Chemotherapeutic
- All-trans retinoic acid (ATRA)
- Interferon α
- Antithymocyte globulin
- Bleomycin
- Carmustine (BCNU)
- Chlorambucil
- Colony-stimulating factors (GM-CSF)
- Cyclophosphamide
- Cytosine arabinoside
- Docetaxel
- Gefitinib
- Gemcitabine
- Interleukin 2
- Irinotecan
- Melphalan
- Mitomycin C
- Paclitaxel

Immunotherapy
- Nivolumab
- Ipilimumab

FAMILY HISTORY

Most forms of ILD are not heritable, although several do have a genetic component. When heritable disease is suspected, it is important to consider both systemic disorders as well as those that primarily affect the lung. In particular, by considering a patient's concomitant medical history or the history of family members, specific diagnoses may be uncovered. Several inborn errors of metabolism (Gaucher disease and Niemann Pick, for example) are inherited in an autosomal recessive fashion. Other rare diseases, such as Hermansky-Pudlak syndrome, Burt-Hogg-Dube syndrome, and neurofibromatosis type I are autosomal dominant disorders.[46] The cystic lung disease LAM may be associated with mutations in the tuberous sclerosis complex (TSC) genes, in which systemic hamartomas are present, including a high incidence of renal angiomyolipomas.[46]

Careful review of family history may reveal first- or second-degree relatives diagnosed with ILD. It is estimated that 2% to 20% of idiopathic interstitial pneumonias are familial, and of these, a large minority are due to mutations in telomerase reverse transcriptase (TERT) and telomerase RNA component (TERC).[47,48] Genome-wide linkage studies have also revealed a common variant in the promoter of the MUC5B gene to be associated with the development of familial and sporadic IPF.[49] The telomere shortening syndromes that lead to dyskeratosis congenita may lead to a phenomenon known as *genetic anticipation*, in which telomere lengths are progressively shortened in subsequent generations. This leads to the earlier onset of more severe disease in each subsequent generation.[50] The recognition of familial ILD related to short telomeres and/or telomere gene mutations is important prognostically since disease progression tends to be more rapid, independent of phenotype.[51] Several other genes have been linked with the onset of IPF, including those involved in the regulation of surfactant protein C.[52] There may be familial predisposition to sarcoidosis, but inheritance is more complex, involving an interaction of genetic and environmental factors.[53]

PHYSICAL EXAMINATION

Most patients with pulmonary fibrosis have lung findings characterized by fine, inspiratory, basilar "Velcro" crackles and many will have digital clubbing. In contrast, patients with nonfibrotic lung disease may have clear lung fields on auscultation. The location of the abnormal breath sounds may be suggestive of the underlying diagnosis, such as upper lobe findings in silicosis, chronic hypersensitivity pneumonitis, and sarcoidosis in contrast to the lower lobe abnormalities in IPF. Additional breath sounds, such as wheezing and inspiratory squeaks, can indicate airway disease, which may focus the examiner's differential diagnosis on airway centered diseases such as bronchiolitis, sarcoidosis, and hypersensitivity pneumonitis. These additional sounds should not be present in a patient with IPF.

Other cardiopulmonary manifestations of disease also should be sought. Signs of pulmonary hypertension and right heart failure include an increased P2 component, right ventricular heave, elevated jugular venous pressure, and lower extremity edema.

Dermatologic and musculoskeletal signs of connective tissue disease, including skin rashes, sclerodactyly, skin thickening, digital ulceration, "mechanic's hands," synovial joint deformities, Raynaud's phenomenon, and telangiectasias, may be extremely helpful in narrowing the differential diagnosis. More specialized examination may include nailfold capillaroscopy which can reveal dilated capillary loops, often seen in systemic sclerosis.[14] Less common findings, such as cutaneous neurofibromas or café au lait spots in neurofibromatosis, albinism and nystagmus in Hermansky-Pudlak syndrome, and facial angiofibromas, periungual fibromas, and Shagreen patch in TSC may all be key features only recognized through a careful and focused search.

CHEST IMAGING

Chest imaging in the patient with suspected ILD includes plain chest radiographs and high-resolution chest computed tomography.

Chest Radiograph

An abnormal chest radiograph is often the first indication of underlying ILD. The pattern and distribution of abnormalities often help in formulating a differential diagnosis (Table 52-4). For example, sarcoidosis, silicosis, and LCH are among the diseases with an upper lobe predominance, while IPF, connective tissue disease–associated ILD, and asbestosis are all lower lobe predominant. Peripheral alveolar opacities are typical findings in organizing pneumonia and chronic eosinophilic pneumonia. The chest radiograph is also helpful for assessing lung volumes. In particular, fibrotic lung disease such as IPF leads to small lung fields, whereas lung volumes are maintained and may even demonstrate hyperinflation in diseases such as LAM and LCH. Hilar fullness observed on chest radiograph may indicate mediastinal and hilar lymphadenopathy, a frequent feature of sarcoidosis and berylliosis.

High-Resolution Chest Computed Tomography

High-resolution computed tomography (HRCT) of the chest is significantly more sensitive than chest radiograph for abnormalities in ILD. The recommended scanning protocol for HRCT includes contiguous or overlapping noncontrast thin-section CT images (<1.5 mm). Initial scans may include supine inspiratory and expiratory imaging to look for evidence of air trapping, as well as prone imaging if position-induced changes in the dependent portions of the lungs are suspected.[54]

TABLE 52-4 Distribution and Pattern of ILD and Mimickers of ILD

Distribution of ILD	
Upper lung zone	**Lower lung zone**
Sarcoidosis	Usual interstitial pneumonia (UIP)
Silicosis	Nonspecific interstitial pneumonia (NSIP)
Coal worker's pneumoconiosis	Connective tissue disease–associated ILD
Hypersensitivity pneumonitis	Asbestosis
Langerhans cell histiocytosis	Desquamative interstitial pneumonia (DIP)
Berylliosis	
Chronic eosinophilic pneumonia	
Pleuroparenchymal fibroelastosis	
Pattern of ILD	
Peripheral reticular	**Ground glass**
Usual interstitial pneumonia	NSIP
Nonspecific interstitial pneumonia	Cryptogenic organizing pneumonia
	Eosinophilic pneumonia (chronic or acute)
	Pulmonary edema
Nodular	Infection (opportunistic or viral)
Sarcoidosis	Alveolar hemorrhage
Berylliosis	Hypersensitivity pneumonitis
Hypersensitivity pneumonitis	Desquamative interstitial pneumonia
Langerhans cell histiocytosis	Sarcoidosis
Silicosis	Pulmonary alveolar proteinosis
Metastatic disease	Mucinous adenocarcinoma
Talcosis	**Cystic**
Granulomatous polyangiitis	Lymphangioleiomyomatosis
Respiratory bronchiolitis–interstitial lung disease	Langerhans cell histiocytosis
	Lymphocytic interstitial pneumonia
	Pneumocystis jiroveci pneumonia

Several radiographic patterns have been identified to help focus the differential diagnosis. In particular, a peripheral reticular pattern that is basilar predominant may be seen in UIP (Fig. 52-2), NSIP (Fig. 52-3), and chronic hypersensitivity pneumonitis. Nodular infiltrates may suggest sarcoidosis (Fig. 52-4), hypersensitivity pneumonitis (Fig. 52-5), and LCH, although the nature of the nodules and their location may make one or another diagnosis more likely. The findings of diffuse cystic abnormalities lead to a specific differential diagnosis, including LAM, LCH, and LIP (Fig. 52-6).[55] The term "ground glass" refers to areas of lung tissues with increased attenuation, but not enough to obscure or distort lung architecture, blood vessels, and lymphatics. Alveolar opacities are a related finding and reflect more dense attenuation of lung tissue, sometimes containing air bronchograms. Many forms of ILD are characterized by ground glass and alveolar opacities. When observed in characteristic distributions, such as the peripheral, patchy, and peribronchovascular alveolar opacities in cryptogenic organizing pneumonia (COP)[56] and chronic eosinophilic pneumonia,[57] they are quite suggestive of an underlying pathologic pattern (Fig. 52-7). However,

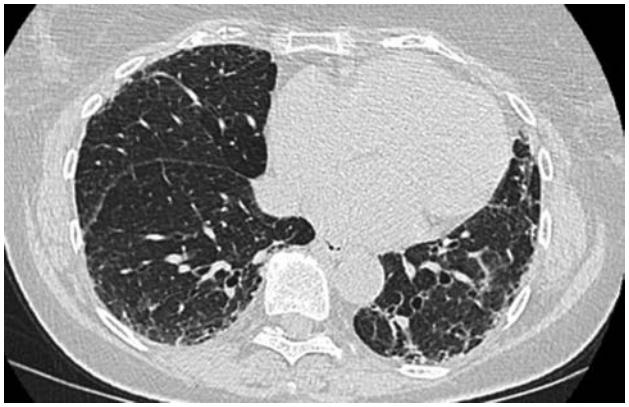


Figure 52-2 High-resolution CT image at the level of the lower thorax of a 67-year-old woman with a 40-pack-year tobacco history. There are bibasilar reticular opacities with traction bronchiolectasis suggesting a radiographic pattern of probable UIP.

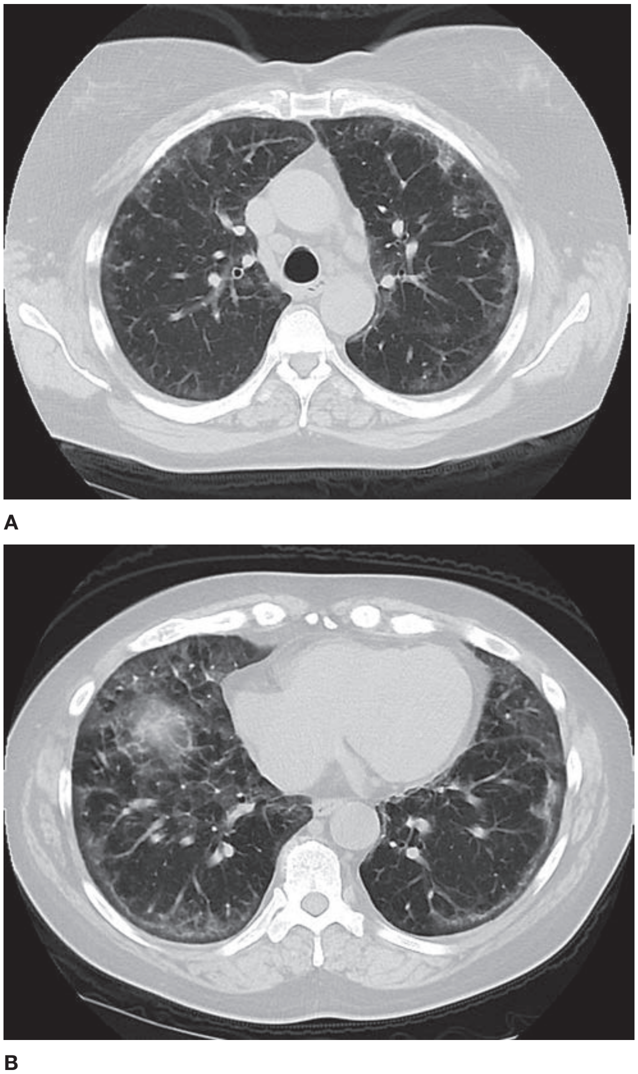

Figure 52-3 A 55-year-old woman with progressive dyspnea on exertion. She had finger swelling and Raynaud's phenomenon, with an antinuclear antibody titer of 1:2560 (nucleolar). Axial CT imaging through the mid (**A**) and lower (**B**) thorax shows ground glass opacities in a peripheral distribution, reticular markings, and mild architectural distortion. Subpleural sparing is evident. These findings are all compatible with a nonspecific interstitial pneumonia (NSIP) pattern. The final diagnosis was scleroderma lung disease.

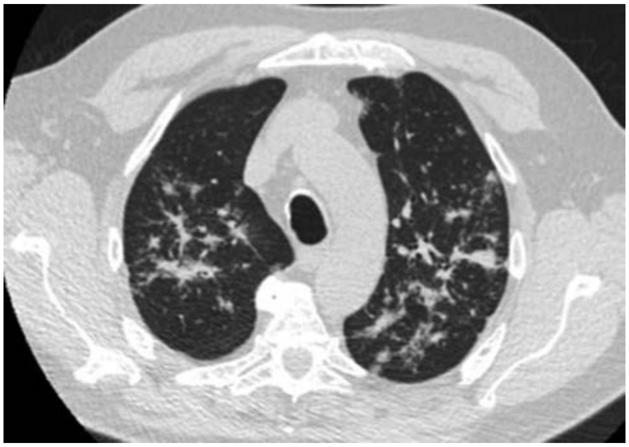

Figure 52-4 A 42-year-old man with sarcoidosis. CT images demonstrate perilymphatic irregular nodular thickening in an upper/mid lung distribution with some areas of mass-like coalescing nodules, more concentrated in the center than at the periphery—the "galaxy sign."

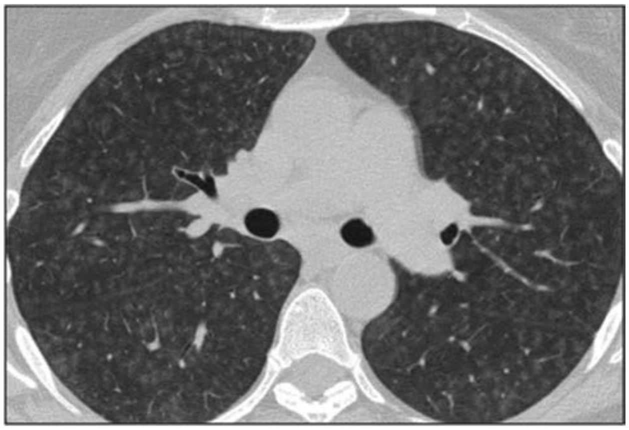

Figure 52-5 High-resolution CT images at the mid thorax level show diffuse ground glass and micronodular changes in a 66-year-old woman with dyspnea and low grade fevers for 3 months. Her hobbies included pottery making; evaluation of her potting shed revealed wet clay contaminated with mold. The patient had resolution of her imaging findings and symptoms once she stopped working with clay.

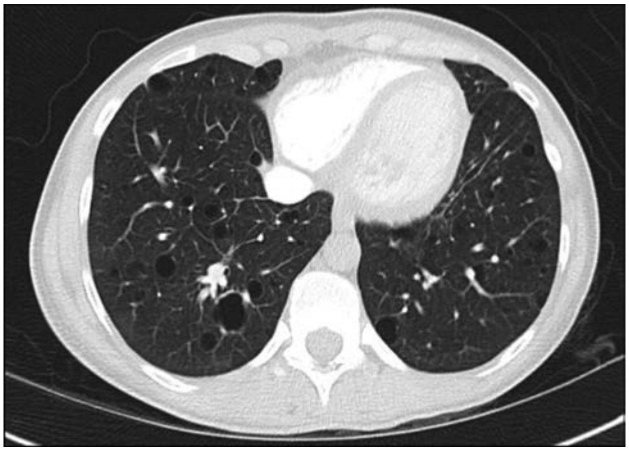

Figure 52-6 A 33-year-old woman with Sjögren syndrome underwent a chest CT with contrast to evaluate for pulmonary embolism. Images at the level of the mid thorax show multiple scattered cysts of variable sizes throughout the lungs suggestive of lymphocytic interstitial pneumonia (LIP).

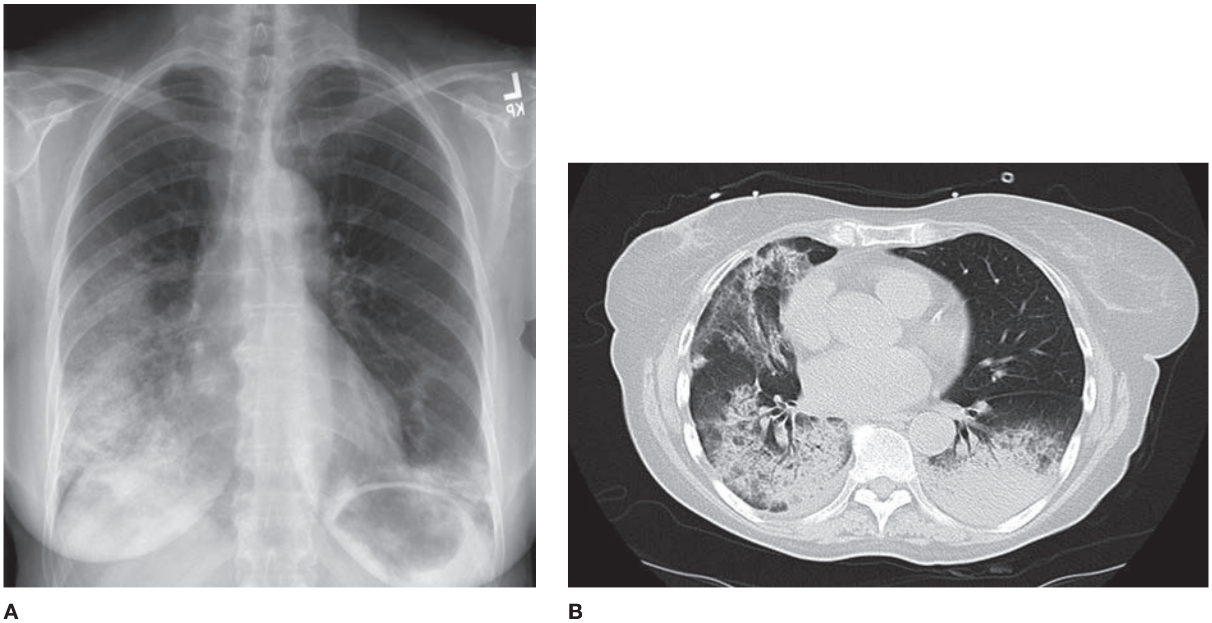

Figure 52-7 A 58-year-old woman with organizing pneumonia (OP) secondary to radiation for breast cancer. Frontal chest radiograph (**A**) demonstrates ground glass and alveolar opacities. High-resolution CT images at the level of the mid (**B**) thorax demonstrate both ground glass opacities and areas of consolidation. She had complete response to corticosteroid therapy.

the radiographic appearance in such cases is nonspecific, and other testing, including lung biopsy, may be required for diagnosis.

Characteristic patterns observed on HRCT can be quite specific in some cases. For example, the characteristic radiographic features of IPF are collectively known as the "UIP pattern" (Fig. 52-8), since these features have been demonstrated to confidently predict the presence of pathologic UIP when surgical biopsy is obtained (Table 52-5).[58,59] This pattern consists of peripheral, subpleural, basilar-predominant reticular opacities in combination with basilar honeycombing and without features, such as ground-glass opacities, cysts or nodules, to suggest another form of ILD.[60] When these features are accurately recognized, patients can be spared a surgical biopsy for diagnosis.

Connective tissue disease–associated ILD can present with a multitude of HRCT patterns including UIP, NSIP, OP, and cystic lung disease. Certain CT signs have been found to be associated with CTD-ILD.[61] Extrapulmonary manifestations of CTD noted on chest imaging include a dilated fluid- or air-filled esophagus (Fig. 52-9). Fibrosis in the anterior upper lobes of the lung, a significant degree of honeycombing, so-called "exuberant honeycombing" (Fig. 52-10), and isolation of fibrosis in the lung bases with a sharp demarcation of normal and abnormal lung parenchyma or the "straight-edge sign"

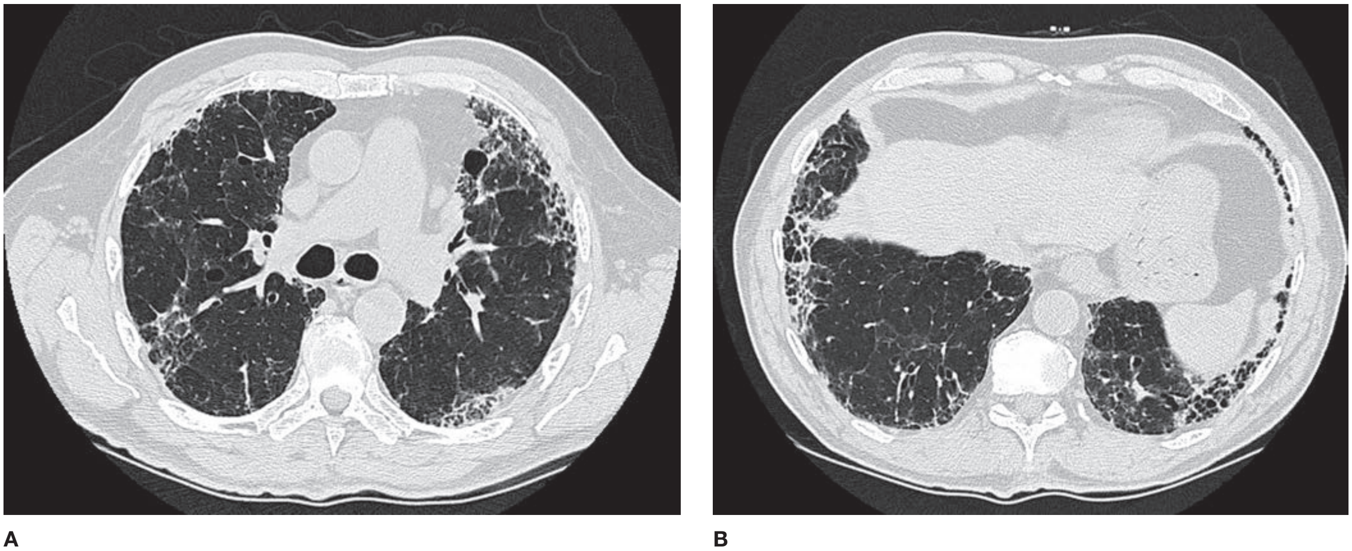

Figure 52-8 An 82-year-old man with progressive dyspnea and a usual interstitial pneumonia (UIP) radiographic pattern. High-resolution (1.25-mm-thick sections) CT images at the level of the mid (**A**) and lower (**B**) thorax show peripheral reticular markings with architectural distortion and small subpleural cysts/honeycombing. Ground glass opacities and other features atypical for IPF are absent. The patient had no exposures and no clinical evidence of connective tissue disease. The final diagnosis was idiopathic pulmonary fibrosis (IPF). No lung biopsy was performed, as a diagnosis was made based upon CT criteria alone.

TABLE 52-5 High-Resolution Computed Tomography Scanning Patterns

UIP	Probable UIP	Indeterminate for UIP	Alternative Diagnosis

Subpleural and basal predominant; distribution is often heterogeneous[a]
Honeycombing with or without peripheral traction bronchiectasis or bronchiolectasis[b]
	Subpleural and basal predominant; distribution is often heterogeneous
	Reticular pattern with peripheral traction bronchiectasis or bronchiolectasis
	May have mild GGO
		Subpleural and basal predominant
		Subtle reticulation; may have mild GGO or distortion ("early UIP pattern")
		CT features and/or distribution of lung fibrosis that do not suggest any specific etiology ("truly indeterminate for UIP")
			Findings suggestive of another diagnosis, including:
			• CT features:
			  • Cysts
			  • Marked mosaic attenuation
			  • Predominant GGO
			  • Profuse micronodules
			  • Centrilobular nodules
			  • Nodules
			  • Consolidation
			• Predominant distribution:
			  • Peribronchovascular
			  • Perilymphatic
			  • Upper or mid-lung
			• Other:
			  • Pleural plaques (consider asbestosis)
			  • Dilated esophagus (consider CTD)
			  • Distal clavicular erosions (consider RA)
			  • Extensive lymph node enlargement (consider other etiologies)
			  • Pleural effusions, pleural thickening (consider CTD/drugs)

Definition of abbreviations: CT, computed tomography; CTD, connective tissue disease; GGO, ground-glass opacities; RA, rheumatoid arthritis; UIP, usual interstitial pneumonia.

[a] *Variants of distribution: occasionally diffuse, may be asymmetrical.*

[b] *Superimposed CT features: mild GGO, reticular pattern, pulmonary ossification.*

Reproduced with permission from Raghu G, Remy-Jardin M, Myers JL, et al. Diagnosis of Idiopathic Pulmonary Fibrosis. An Official ATS/ERS/JRS/ALAT Clinical Practice Guideline. Am J Respir Crit Care Med. 2018;198(5):e44–e68.

(Fig. 52-11) are often noted in connective tissue disease associated UIP (Table 52-6). In addition, HRCT features consistent with NSIP and OP overlap are suggestive of an underlying connective tissue disease such as the idiopathic inflammatory myopathies.[62]

Radiologic features of hypersensitivity pneumonitis vary based on the histopathologic stage of disease. Recent guidelines have focused on two patterns: fibrotic and non-fibrotic HP. Features highly suggestive of fibrotic HP can include a combination of fibrotic changes (reticulations, traction bronchiectasis, or honeycombing) in combination with airway-centered disease (Fig. 52-12). It is important to note that the distribution of radiologic findings in fibrotic HP is highly varied and can present as central, peripheral, apical, or basal-predominant disease. In contrast, nonfibrotic HP often presents with diffuse ground glass opacities, centrilobular nodules, and mosaic attenuation (Fig. 52-5).[5]

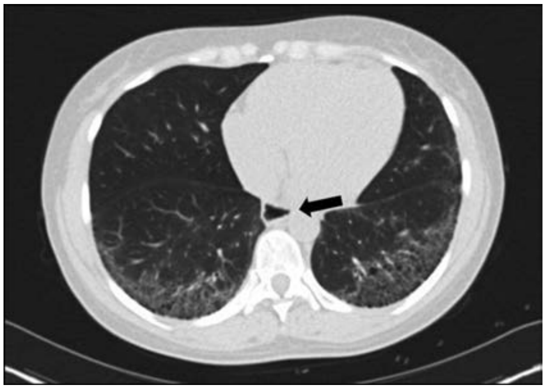

Figure 52-9 High-resolution CT image shows a dilated, air-filled esophagus *(arrow)* and bibasilar ground glass opacities suggesting fibrotic NSIP in a 47-year-old woman with systemic sclerosis.

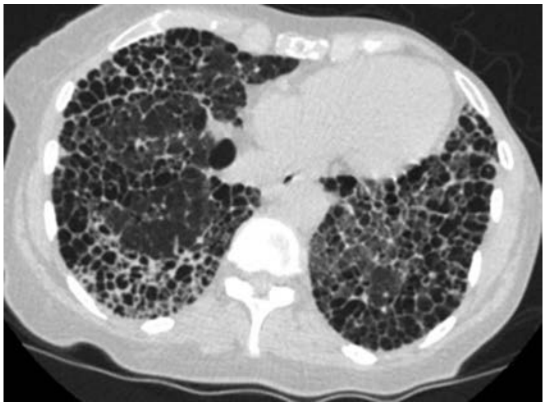

Figure 52-10 High-resolution CT images with bibasilar "exuberant honeycombing" in a 67-year-old woman with long-standing rheumatoid arthritis. Notice that honeycomb cysts constitute nearly all of the fibrotic regions of the lungs on this cross section.

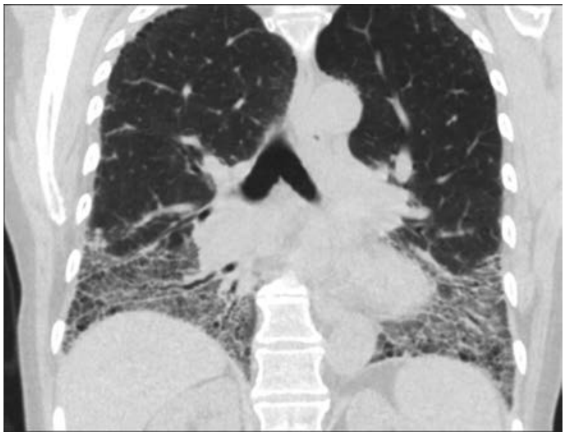

Figure 52-11 Coronal CT image from a 49-year-old woman with systemic sclerosis showing lower lobe–predominant reticular and ground glass changes with a sharp demarcation in the craniocaudal plane indicative of the "straight-edge sign."

TABLE 52-6 Radiographic Signs in ILD

Anterior upper lobe sign	Concentration of fibrosis within the anterior aspect of the upper lobes and concomitant lower lobe involvement	Suggests collagen vascular disease
Exuberant honeycombing	Honeycomb cyst formation within the lungs constituting >70% of fibrotic portions of lung	
Straight edge sign	Isolation of fibrosis to the lung bases with sharp demarcation in the craniocaudal plane without substantial extension along the lateral margins	
Three-density sign/ headcheese	Juxtaposition of lobular regions of low, normal, and high attenuation indicative of a mixed infiltrative and obstructive process	Suggests subacute hypersensitivity pneumonitis
Atoll sign/reverse halo	Central ground glass opacity surrounded by denser consolidation in the shape of a crescent or ring	Suggests cryptogenic organizing pneumonia
Galaxy sign	Mass-like lesion composed of coalescing granulomatous nodules more concentrated in the center than at the periphery	Suggests sarcoidosis

Data from Chung JH, Cox CW, Montner SM, et al. CT Features of the usual interstitial pneumonia pattern: differentiating connective tissue disease-associated interstitial lung disease from idiopathic pulmonary fibrosis. AJR Am J Roentgenol. 2018;210(2):307–313.

In patients with a smoking history, HRCT has led to clinical recognition of the simultaneous occurrence of emphysema and pulmonary fibrosis or combined pulmonary fibrosis and emphysema (CPFE) (Fig. 52-13). These patients are often noted to have an increased incidence of pulmonary hypertension. Chest imaging has also revealed an increased incidence of non–small-cell lung cancer in patients with fibrotic lung disease. Malignancy is often noted to arise in a peripheral distribution, developing in areas of honeycomb change or the border between fibrotic and nonfibrotic areas.[63]

LABORATORY TESTING

Routine laboratory testing, while often normal, may lead to the diagnosis of a previously unrecognized systemic disease, or may be suggestive of the underlying lung disease, particularly in the case of connective tissue disease.[64] More advanced testing is often necessary, including serologic testing for underlying connective tissue disease (Table 52-7). Many of the tests listed here are employed by ILD centers in the evaluation of patients newly presenting with diffuse lung disease, although no clear standard exists. Importantly, ILD can be the sole manifestation or the presenting feature of a connective tissue disease, making a careful evaluation for previously unrecognized autoimmune disease essential.

Most pulmonologists have encountered patients with idiopathic interstitial pneumonia as well as clinical features or serologic abnormalities that suggest, but are not diagnostic of, a connective tissue disease. In 2015, the ERS/ATS task force on undifferentiated forms of connective tissue disease–associated ILD suggested the nomenclature of interstitial pneumonia with autoimmune features (IPAF),

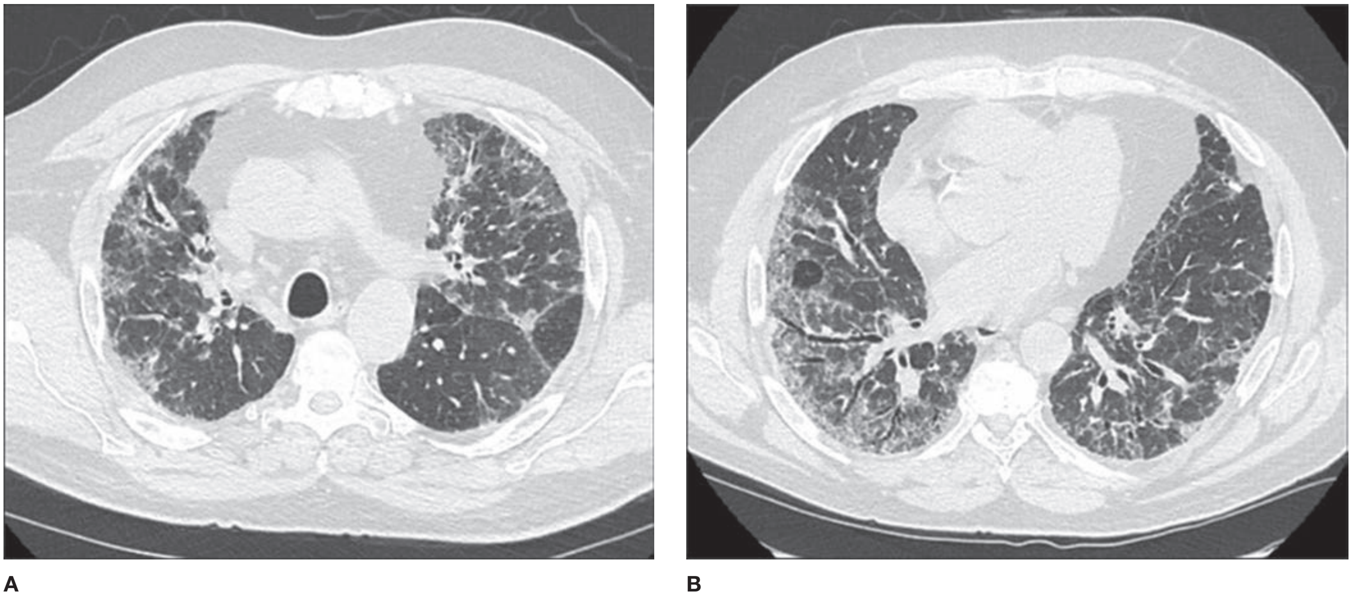

Figure 52-12 A 56-year-old woman presented with chronic cough and dyspnea on exertion. She suspected chronic mold exposure due to recurrent water damage in her basement. CT images through the mid-thorax (**A**) and lower thorax (**B**) reveal upper and lower lobe reticular changes with mild ground glass opacities. Traction bronchiectasis with both peripheral and peribronchovascular distribution is noted in the upper and lower lobes. Mosaicism is seen in the lower lobes. Pathologic findings of loosely formed granulomas along with clinical history and imaging findings are strongly suggestive of fibrotic hypersensitivity pneumonitis.

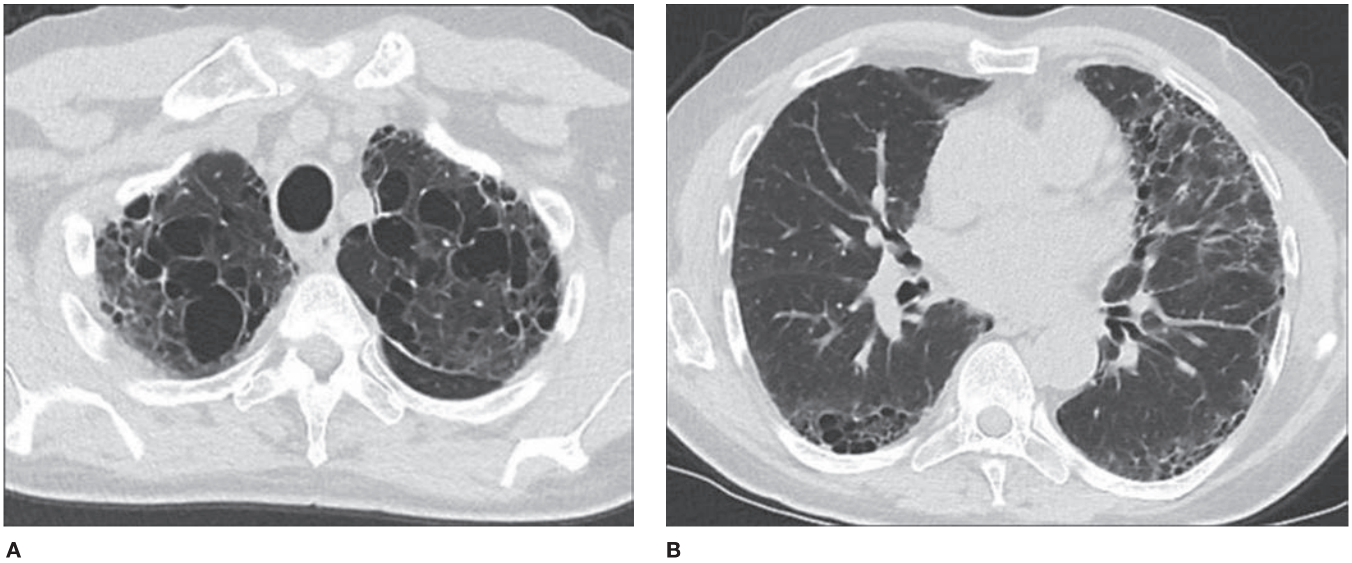

Figure 52-13 A 69-year-old former smoker with progressive dyspnea and a pattern of combined pulmonary fibrosis and emphysema (CPFE). High-resolution CT images at the level of the upper thorax (**A**) and lower thorax (**B**) show centrilobular emphysema in the upper lobes and bibasilar reticular changes with honeycombing. Pulmonary function testing revealed normal expiratory flow rates and lung volumes, but with a marked reduction in $D_{L_{CO}}$.

as well as a classification system. Patients with IPAF have ILD with no other etiology, do not meet criteria for a specific CTD, and have certain features of autoimmunity. Examples include physical examination findings of skin and joint abnormalities (inflammatory arthritis, mechanic's hands, Raynaud's phenomenon), positive autoimmune serologies, and HRCT or lung biopsy findings suggesting patterns frequently associated with CTD-ILD. It is important to note that this classification scheme is a research statement and specifically does not include guidelines on clinical care, diagnostic testing, or management of patients who meet criteria for IPAF.[65]

TABLE 52-7 Serologic Testing in ILD

Test	Disease
ANA	SLE, Scleroderma, MCTD
SSA/Anti-Ro	Sjögren syndrome, inflammatory myopathies
SSB/Anti-La	Sjögren syndrome

Proteinase 3 antibody	

The importance of laboratory evaluation may also lie in the discovery of associated conditions, such as transaminitis or hypercalcemia in sarcoidosis,[66] or renal insufficiency in pulmonary renal syndromes and other connective tissue disease with renal involvement. Other examples include the presence of peripheral eosinophilia in chronic eosinophilic pneumonia, eosinophilic granulomatosis with polyangiitis, drug reaction, and other forms of vasculitis. Serum IgG testing against potential antigens associated with HP may result in further exploration of a causative agent in the patient's environment and strengthen a diagnosis of HP, but their role in routine ILD evaluation is still controversial and warrants further study.[5,67]

Anemia may worsen symptoms of dyspnea in the setting of ILD and may reflect an underlying hemolytic condition, or chronic gastrointestinal blood loss in inflammatory bowel disease. Elevated creatinine kinase and aldolase may indicate ongoing muscle damage from an idiopathic inflammatory myopathy. In addition to eliciting causes for the ILD, recognition of underlying chronic organ dysfunction will also help determine the ability of the patient to tolerate treatment.

PULMONARY FUNCTION TESTING

Pulmonary function tests (PFTs) are a mainstay in the pulmonologist's armamentarium in the evaluation and management of ILD. Importantly, they assist in assessing the severity of disease and help determine prognosis in many forms of disease.[68–70] PFTs are a relatively noninvasive method to gauge disease progression and measure response to therapy.[71] The testing typically includes spirometry, measurement of lung volumes, and diffusing capacity (Chapter 31). In certain cases, maximal inspiratory and expiratory pressures (MIPS and MEPS) are useful in the assessment of respiratory muscle strength, which may be compromised in myositis-associated ILD. Exercise testing, such as a 6-min walk test, is particularly important for patients with ILD as resting oxygenation does not reflect exertional oxygen requirements.

Typically, spirometry in most forms of ILD demonstrates a restrictive ventilatory defect due to decreased compliance and increased recoil of the lung parenchyma.[72] Forced vital capacity

(FVC) is a commonly used marker of lung function decline. It is the most commonly utilized outcome measure in clinical trials for IPF and other forms of fibrotic ILD.[73] The presence of obstruction suggests either concomitant obstructive lung disease, often from prior smoking exposure, or the presence of an airway-centered ILD such as LCH, LAM, or sarcoidosis. Decreased static lung volumes confirm the presence of restriction. In the case of airway centered diseases, the lung volume measurements may indicate unrecognized air trapping and hyperinflation. In cases of combined pulmonary fibrosis and emphysema, lung volumes may appear within normal range due to combined hyperinflation and restriction, but a markedly impaired diffusing capacity can be a clue to the true severity of the disease process.

Diffusion impairment, demonstrated by a decrement in the diffusion capacity (DL$_{CO}$), is frequently observed in ILD and is often the earliest physiologic abnormality.[74] The decreased DL$_{CO}$ reflects the presence of either fibrotic tissue or inflammatory cells (or both) in the interstitium, leading to a defect at the level of the alveolar-capillary membrane. The diffusion impairment is typically lower than predicted by alveolar volume.[72] An impairment in diffusion can also be seen with anemia and pulmonary hypertension, the latter of which should be suspected when there is a decline that cannot be explained by worsening ILD.

Both FVC and DL$_{CO}$ have been utilized in creating a staging system for IPF known as the GAP index. This score estimates mortality in years, based on patient gender, age and degree of physiologic impairment using FVC and DL$_{CO}$. The simplicity of this calculation allows for real time estimation of individual risk and change in clinical decision-making.[75] The addition of resting or exertional hypoxemia to this calculation improves 1-year mortality/transplantation prediction.[76]

Formal 6-min walk testing is quite useful, demonstrating oxygen requirements with exercise and additionally offering an assessment of exercise capacity in terms of distance walked, heart rate response, and causes for exercise discontinuation (including leg discomfort or chest pain). In addition to prognostication in IPF, it may predict prognosis in other forms of ILD as well.[77–79] If this is not available, measurement of pulse oximetry with ambulation in the clinic or with stair climbing can offer important information, including an understanding of reasons for the patient's dyspnea as well as a marker of disease severity.

BRONCHOSCOPY

Core elements in the bronchoscopic evaluation of ILD include bronchoalveolar lavage and transbronchial biopsy. More recently, transbronchial cryobiopsy has been added to the diagnostic armamentarium.

Bronchoalveolar Lavage

The simplest and least invasive assessment during bronchoscopy is the sampling of protein and cellular components of lung fluid via bronchoalveolar lavage (BAL). Tests typically performed on this fluid include cell count and differential, cytology, and a variety of viral assays and microbiologic cultures depending on the clinical scenario. In certain cases, gross inspection of fluid collected may lead to a diagnosis. For example, return of progressively bloody lavage specimens may suggest diffuse alveolar hemorrhage (DAH).[80] The presence of milky white BAL fluid with debris that settles out within 15 to 20 min would suggest a diagnosis of pulmonary alveolar proteinosis in the right clinical settings, confirmed by periodic acid-Schiff (PAS) staining.[81] BAL cellular analysis may be useful in narrowing the differential diagnosis of certain ILDs. Notably, an eosinophil differential count >25% is virtually diagnostic of acute or chronic eosinophilic pneumonia. A lymphocyte differential count >25% suggests granulomatous diseases (sarcoidosis, hypersensitivity pneumonitis, or chronic beryllium disease), NSIP, drug reaction, LIP, COP, or lymphoma.[80,82] Further investigation with flow cytometry can lead to diagnoses such as LCH and lymphoid malignancies, as well as allow characterization of T helper (CD4$^+$) and T suppressor (CD8$^+$) subsets. In the case of sarcoidosis, BAL lymphocytosis and a CD4$^+$/CD8$^+$ ratio greater than 4 may increase confidence in the diagnosis. Lymphocyte analysis may also play a role in distinguishing fibrotic HP from IPF and sarcoidosis, although specific lymphocyte count thresholds have not been established.[5]

Transbronchial Lung Biopsy

Bronchoscopy with transbronchial biopsy is a generally well-tolerated procedure than can be useful in the diagnosis of certain ILDs. The risk of pneumothorax is approximately 1% and significant bleeding less than 2%.[83,84] Biopsy forceps are introduced via the flexible bronchoscope, and tissue samples are obtained with fluoroscopic guidance. Multiple passes are made, with yield improving when more than four specimens are obtained.[85] Despite the relatively small size of these specimens as compared with cryobiopsy and surgical lung biopsy (see below), diagnostic information in certain forms of ILD are particularly amenable to diagnosis by bronchoscopy. This is especially true for granulomatous diseases such as sarcoidosis, hypersensitivity pneumonitis, and drug toxicity as well as in situations where non-ILD diagnoses are likely such as infection and malignancy.[86] The diagnosis of sarcoidosis is enhanced by the addition of endobronchial ultrasound (EBUS)-guided aspiration of mediastinal and hilar lymph nodes.[6] Newer technology such as genomic testing on transbronchial tissue specimens has been used to differentiate usual interstitial pneumonia from non-UIP when a surgical lung biopsy is not possible. The role of this biomarker in the diagnosis of fibrotic ILD is still in evolution but may play a role, particularly when the CT pattern is "indeterminate for UIP."[87,88]

Transbronchial Cryobiopsy

Transbronchial cryobiopsy is a bronchoscopic biopsy technique (Chapter 34) that can provide larger and better-preserved tissue samples compared with those obtained using traditional biopsy forceps. A cryoprobe, consisting of a long flexible insulated catheter with blunt metal tip, is advanced through the working channel of the bronchoscope into the peripheral lung. A compressed gas, such as CO_2, is released at a high flow rate into the tip of the probe, causing surrounding tissue to rapidly freeze and adhere to the cryoprobe tip. The bronchoscope and cryoprobe with attached frozen tissue are then removed en-bloc from the airway. Resulting biopsies tend to be 7 to 10 mm and notably lack crush artifact.[89]

Cryobiopsy appears to have a lower rate of mortality and acute exacerbation compared with surgical lung biopsy.[90] Several experts suggest biopsy of at least two different sites, which can be in the same lobe or different lobes. While this increases diagnostic yield, it is associated with a substantially higher risk of pneumothorax compared with cryobiopsy of one site. Comparison of transbronchial cryobiopsy and surgical lung biopsy tissue from ipsilateral lobes obtained from the same patient has shown good histopathologic agreement between the two biopsy modes, although the risk of mild to moderate airway bleeding from cryobiopsy is about 20%.[91] While some studies suggest an increase in diagnostic confidence with cryobiopsy, its role in the diagnosis of ILD is also in evolution and it is not yet a recommended part of society guidelines.[92,93]

SURGICAL LUNG BIOPSY

Despite a high yield in certain forms of lung disease, the utility of transbronchial biopsy for most of the idiopathic interstitial pneumonias (such as IPF, NSIP, and LIP) is low, and cryobiopsy may not be the preferred technique due to lack of expertise or unfavorable patient characteristics. In this case, a surgical biopsy is often

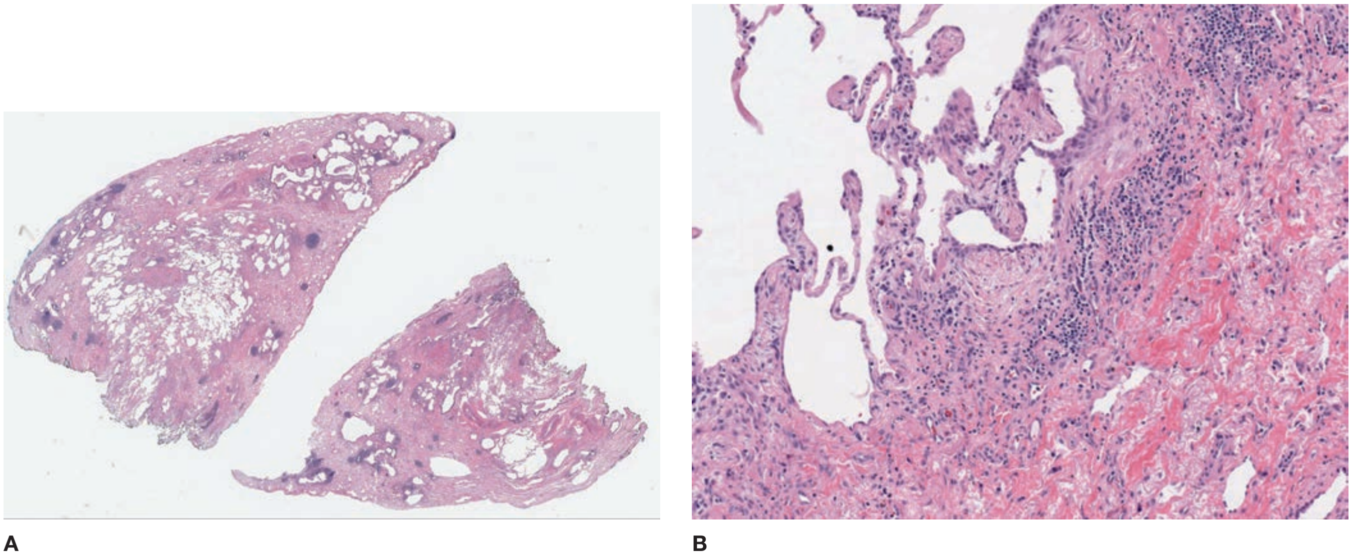

Figure 52-14 Usual interstitial pneumonia (UIP). There is heterogeneous fibrosis, which affects the periphery of the lung (**A**) when seen on low-power view. The fibroblastic foci (**B**) are the hallmark of the UIP pattern. *(Reproduced with permission from Robert Homer, MD, PhD, Yale School of Medicine.)*

required for accurate diagnosis, performed as video-assisted thoracoscopic surgery (VATS).[94]

VATS has a low morbidity and mortality in selected populations but should be performed by surgeons familiar with the techniques needed for ILD diagnosis.[95,96] Wedge biopsies are taken from three separate lobes and should include areas of normal-appearing lung; when only the most fibrotic appearing areas are sampled, specimens may not capture the active histologic pattern and show only nonspecific fibrosis. Risks of VATS include prolonged air leak, bleeding, infection, and incisional site pain.[97] Generally, the length of hospital stay after a VATS procedure is 2 to 3 days though some centers have reported even shorter stays in selected patients.[96]

For most patients, there is no significant loss of lung function; however, cases of acute exacerbation of ILD following biopsy have been reported.[97,98] Patients must be able to tolerate general anesthesia with single lung ventilation.[97] Risk factors for complications and mortality include advanced respiratory failure as indicated by high P_{CO_2} and/or severe hypoxemia, significant pulmonary hypertension, problems with clotting, and immunosuppression.[99–101] Patients older than 65 years of age have morbidity and mortality rates no different from younger patients, although those over 75 may have higher rates of air leak.[102,103] Preoperative cardiac evaluation should be considered since many patients undergoing biopsy for ILD are older or have a significant smoking history.[103]

PATHOLOGY

Several major pathologic patterns are described in the idiopathic interstitial pneumonias, including granulomatous ILD, UIP, NSIP, and organizing pneumonia. However, these same patterns may be observed in patients with systemic diseases and other causes for ILD, and therefore the pathology must be interpreted within the context of the clinical scenario and radiographic studies.

The UIP pattern is the histologic correlate of IPF and has specific features, including a heterogenous appearance in which areas of fibrosis and honeycombing are interspersed with areas of normal lung (Fig. 52-14). The changes are most pronounced in the periphery of the lung and should not predominantly involve the airways. Fibroblastic foci should be present and atypical features should be absent. The most recent guidelines offer categories in which the pathologist may interpret the pattern as "UIP," "probable UIP," "indeterminate for UIP," and "alternative diagnosis."[54] These, in combination with the HRCT and clinical features, will lead to a clinical diagnosis of IPF, "likely" IPF, non-IPF, and indeterminate for IPF. However, the clinical context must always be considered as a UIP pattern is not completely specific for IPF. For example, a patient with a prolonged history of bird exposure, whose HRCT demonstrates upper lobe predominance with lobular areas of air trapping, may have UIP on biopsy, but the final diagnosis will be chronic hypersensitivity pneumonitis. A patient with morning stiffness, deforming arthritis, high-titer anti-CCP antibodies, and UIP will be given a diagnosis of rheumatoid arthritis–associated ILD.

Nonspecific interstitial pneumonia (NSIP) is characterized by interstitial inflammation and fibrosis in a homogenous pattern, as opposed to the heterogeneity of UIP (Fig. 52-15). It may range

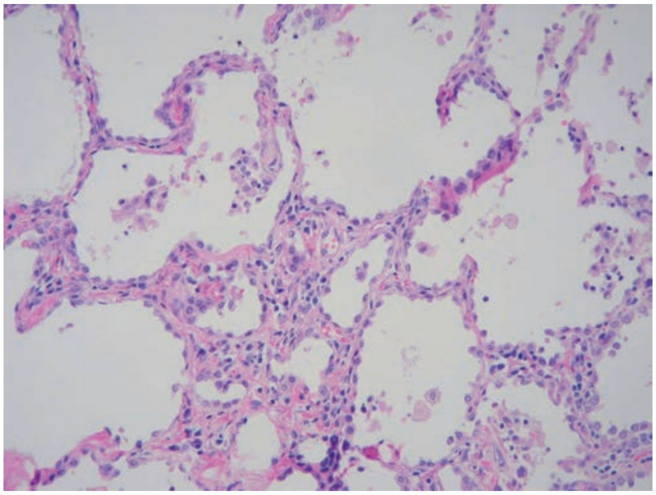

Figure 52-15 Nonspecific interstitial pneumonia (NSIP). There is diffuse, homogeneous septal fibrosis with a mild mononuclear infiltrate, as well as mild diffuse type II cell hypertrophy. No organizing pneumonitis, fibroblast foci, granulomas, or eosinophilic infiltrate are seen. Honeycombing is absent. There is a very mild accumulation of alveolar macrophages in the alveoli. *(Reproduced with permission from Robert Homer, MD, PhD, Yale School of Medicine.)*

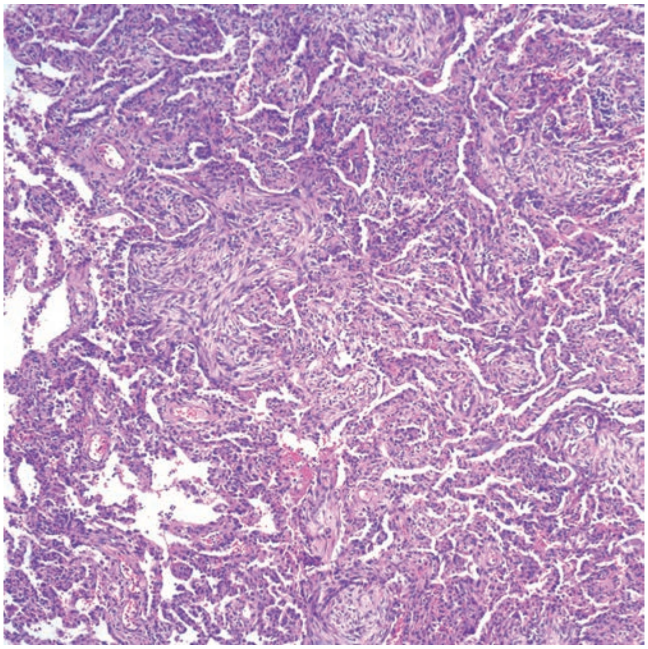

Figure 52-16 Organizing pneumonia (OP). There is fibromyxoid granulation tissue within alveolar ducts accompanied by a lymphoplasmacytic infiltrate. Notable is the absence of hyaline membranes, necrosis, neutrophilic or eosinophilic infiltrate, granulomas, and established fibrosis. *(Reproduced with permission from Robert Homer, MD, PhD, Yale School of Medicine.)*

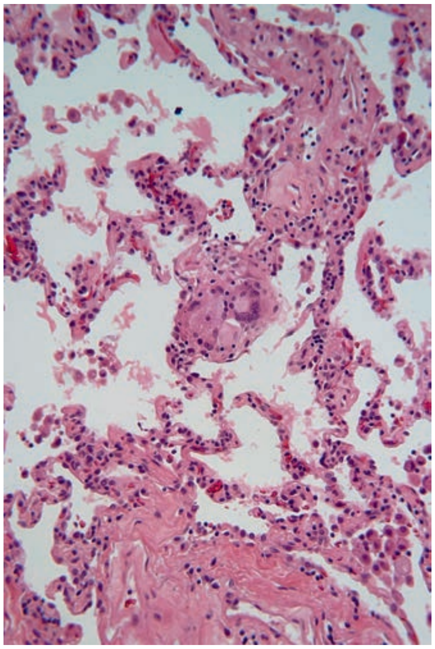

Figure 52-17 Hypersensitivity pneumonitis. There are loosely formed granulomas with background pneumonitis, including patchy lymphoplasmacytic infiltrate in the interstitium and organizing pneumonitis. *(Reproduced with permission from Robert Homer, MD, PhD, Yale School of Medicine.)*

from predominantly cellular to fibrotic in nature, with interstitial thickening but without significant honeycomb change.[104] While this pattern may be idiopathic, it is much more commonly associated with connective tissue disease; in this setting, the prognosis is better than that of idiopathic NSIP.[105] For example, a patient with a history of Raynaud's syndrome, skin thickening, esophageal dysmotility, SCL-70 antibody, and diffuse ground glass opacities on HRCT, and pathologic NSIP will be given a diagnosis of systemic sclerosis–related ILD, although biopsy would be unlikely to be indicated in this clinical scenario.

Organizing pneumonia is characterized histopathologically by intra-alveolar granulation tissue containing myofibroblasts and connective tissue (Fig. 52-16). The finding of organizing pneumonia on histopathology should prompt an exhaustive search for a cause before being called cryptogenic organizing pneumonia (COP), which is truly idiopathic. For example, a patient with peripheral alveolar opacities on chest imaging and features of OP on biopsy who is found to have taken chronic nitrofurantoin as suppressive therapy for urinary tract infections may be suffering from drug toxicity. Likewise, a patient with OP who has muscle weakness, papular lesions on the hands, and heliotrope rash likely carries a diagnosis of dermatomyositis.

Granulomatous histology may be observed in idiopathic disease, such as sarcoidosis, but it may be present in many other forms of ILD, including drug toxicity and hypersensitivity pneumonitis[106] (Fig. 52-17). In addition to ILD, the possibility of diffuse infections, including mycobacterial disease, must always be kept in mind. The morphology and location of the granulomas, as well as the appearance of the surrounding tissue, must be considered in combination with clinical features.[107] For example, a history of beryllium exposure in combination with sarcoidal granulomas on pathology will change the diagnosis from sarcoidosis to chronic beryllium disease. A patient with diffuse centrilobular ground glass nodules, a history of humidifier use, and loosely formed granulomas on histology most likely carries a diagnosis of subacute hypersensitivity pneumonitis.

THE ROLE OF MULTIDISCIPLINARY DISCUSSION

The diagnosis of interstitial lung disease is often an iterative process. A comprehensive approach including the clinical history, laboratory testing, and radiographic appearance can help assess if pathologic information is needed for accurate diagnosis. In cases of underlying connective tissue disease or a temporally correlated drug or environmental exposure, pathologic tissue may not change management and may not be worth the operative risk. Similarly, specific features on HRCT are highly predictive of the histopathologic finding of UIP by experienced observers and can spare many patients a surgical biopsy in the correct clinical setting.[54]

It has been demonstrated that the final diagnosis will often change after a group discussion involving clinicians, radiologists, and pathologists better known as multidisciplinary discussion (MDD).[108] The diagnosis also frequently differs between academic and community-based physicians, with academic physicians being less likely to arrive at a diagnosis of IPF.[109] In addition to providing a new diagnosis in a significant proportion of cases, MDD may be particularly valuable in management decisions for non-IPF ILD.[110] Remote MDD may be an option in some cases.[111]

TREATMENT

Approach to treatment includes general and specific measures, as discussed below.

■ Removal from Exposures

The treatment of ILD varies with the specific diagnosis. Importantly, if any causative exposure can be identified, this should be eliminated. For example, if a drug reaction is suspected, that drug should be discontinued. For environmental exposures, the situation may require more extensive remediation.[112] For example, in addition to removal of birds from the home, extensive cleaning of upholstery, window coverings, and ventilation systems may be required. The cleaning should not be performed by the patient. Even these measures may not remove all residual antigen, and removal of the patient from the location may be necessary.[113] In the case of extensive water damage and mold growth, significant demolition and reconstruction may be necessary. In the case of occupational exposures, some situations may be addressed by altering the particular job being done by the patient, changing the substances used, or using protective respiratory equipment, but others may require complete removal from the suspected exposure.[114] In many cases, patients' livelihoods may be at stake, involving severe financial consequences, disability, and workers' compensation. Identification of a workplace hazard for a patient may lead to the discovery of a public health issue or one that affects the health of coworkers.[115] Referral to and coordination with an occupational medicine specialist may be necessary to appropriately assess and remediate home and workplace exposures.[27]

■ Immunosuppressive Therapy

Some forms of ILD, including COP, connective tissue disease–associated ILD, and sarcoidosis, may demonstrate a favorable response to corticosteroids and other immunosuppressive agents.[116] However, in diseases such as IPF, immunosuppression has been demonstrated to carry harm without potential benefit.[117] When considering the use of these drugs, an assessment should be made regarding the likelihood of response as well as the relative risks and benefits of the therapy.

The many side effects of corticosteroids include glucose intolerance, bone loss, cataract development, and mood instability.[118] Increased risk of infection may be substantial.[119] Some inflammatory diseases such as COP, CEP, and subacute hypersensitivity pneumonitis can be quite sensitive to corticosteroids; relatively quick weaning to low dosages may be feasible and effective. In disorders such as connective tissue disease–associated ILD, when a more prolonged course of therapy is anticipated, the early addition of steroid-sparing medications, such as azathioprine or mycophenolate mofetil, can permit lower doses of corticosteroids to be used.[120] High doses of steroids have been implicated in renal crisis and should be avoided in patients with scleroderma.[121] Certain forms of ILD, including scleroderma lung disease, vasculitis with alveolar hemorrhage, and severe cases of connective tissue disease–associated ILD, may require drugs such as rituximab and cyclophosphamide, the latter of which carries increased risk for severe side effects and infertility. Such medications should only be prescribed by practitioners familiar with use and toxicities of these agents.

When actively treating ILD, objective measures of improvement, including PFTs, exercise oximetry, and chest radiography should be employed to avoid the unnecessary continuation of therapy. In particular, when corticosteroids are used, there is often an initial boost in mood and energy level that may not correspond to actual improvements in lung function. If no clinical improvement is seen after 3 to 6 months of therapy, change or discontinuation of immunosuppressive therapy should be strongly considered.

■ Antifibrotic Drugs

Clinical trials have resulted in FDA approval of two antifibrotic drugs, aimed at slowing decline in lung function from progressive fibrotic lung diseases. Pirfenidone, a small molecule drug with antifibrotic properties, is approved for the treatment of IPF in the United States as well as around the world.[122] Nintedanib, which is a tyrosine kinase inhibitor against fibroblast growth factor receptor (FGF-R), vascular endothelial growth factor receptor (VEGF-R), and platelet-derived growth factor receptor (PDGF-R), has been shown to slow the decline in lung function in IPF, scleroderma-associated ILD, and progressive fibrotic lung disease and is approved in the United States for the treatment of all.[123–125] In some situations, for example in scleroderma, patients may be treated with both immunosuppressive and antifibrotic medications.[120]

■ Future Therapeutics

There are multiple phase 3 clinical trials underway to assess the efficacy of novel agents for the treatment of IPF. PRM-151, a recombinant form of human pentraxin 2 protein, inhibits the differentiation of monocyte-derived fibrocytes, promotes the formation of immunoregulatory macrophages, and inhibits neutrophil adhesion to extracellular matrix proteins. Phase 2 clinical trial data have suggested a slowing of decline in lung function in combination with standard of care therapies when compared with standard of care alone.[126] Pamrevlumab (FG-3019) is an antibody that binds to connective tissue growth factor and inactivates it. Phase 2 trial data suggest that infusion therapy with this treatment attenuates the progression of IPF, and advanced clinical trials are currently underway.[127] Many other promising agents are being studied. Future therapeutic strategies may seek to inhibit multiple pathways simultaneously via combination therapy.

■ Supportive Therapy

Supportive therapy directed at improving quality of life and decreasing respiratory symptoms should be a part of the approach to care of all patients with ILD. Formal exercise testing in the PFT laboratory offers a standardized approach to the assessment of oxygen needs. However, a check of oximetry with simple ambulation in the hallway or with stair climbing can uncover the need for oxygen supplementation. Hypoxemia with oxygen saturation less than or equal to 88% at rest is an indication for long-term oxygen therapy for at least 15 hours a day.[128] Portable oxygen tanks and battery-powered portable oxygen concentrators are often prescribed for ILD patients with exertional hypoxemia to encourage mobility. Collaboration among physicians, patients, and oxygen providers can help identify the ideal system for each patient. Future randomized controlled trials assessing the impact of oxygen therapy in fibrotic ILD patients are underway.[129]

The role of pulmonary rehabilitation has been studied in chronic obstructive lung disease and leads to increased muscle strength and improved endurance.[130] Similar improvements may be evident in the fibrotic lung diseases.[131,132] In addition to the potential benefits of improved muscle strength and stamina, patients with ILD may also benefit from the ongoing education regarding oxygen use, breathing and pacing techniques, and social support.[133] As patients with chronic lung disease frequently suffer from anxiety and depression, pulmonary rehabilitation may benefit patients by identifying these issues, leading to appropriate specialist referrals.[134] Questionnaires that specifically assess health-related quality of life in ILD patients include the Living with IPF (L-IPF) questionnaire and the King's Brief Interstitial Lung Disease (KBILD) questionnaire.[135,136]

■ Treatment of Comorbidities

Several common comorbidities should be sought among patients with ILD. In particular, an assessment for underlying coronary artery disease should be undertaken when dyspnea on exertion is present, as the risk for ischemic heart disease is increased among patients with IPF.[137,138] Due in part to prior tobacco exposure, patients with progressive fibrotic lung disease have an increased risk of developing lung cancer.[139] Nodules should be individually assessed based on size, appearance, and growth. No specific screening recommendations for this patient population exist apart from those based on smoking history. The prevalence of obstructive sleep apnea appears to be quite high among patients with ILD, even in the absence of excessive sleepiness or large body habitus, although these features are important to assess.[140–142] There is a high prevalence of gastroesophageal reflux (GERD) among patients with IPF, although only a minority have symptoms.[143,144] Studies have suggested that GERD may be intimately involved in the pathogenesis of IPF and may be linked with progression of disease.[145] The evaluation and treatment of GERD in patients with ILD is an evolving field. Based on existing data, it is not clear how aggressive therapy should be. If symptoms such as heartburn, regurgitation, or severe cough exist, therapy is typically utilized. However, whether to seek evidence of asymptomatic GERD through more invasive testing and whether to treat such patients is not clear.[139]

In addition to native comorbidities, side effects from therapy should be assessed. In particular, the use of corticosteroids can lead to weight gain, fluid retention, diabetes, and osteoporosis. Glucocorticoid-induced osteoporosis may be prevented by the use of calcium and vitamin D supplementation early in the course of steroid use.[146] Fracture risk assessment can identify patients in whom bisphosphonate therapy is indicated.

Pulmonary hypertension develops in a significant number of patients with ILD and may be due to the effects of chronic hypoxia and the focal destruction of capillaries in the fibrotic lung tissue.[147] This is classified by the World Health Organization as group 3 pulmonary hypertension. Pulmonary hypertension contributes to progressive diffusion impairment and may contribute to progressive respiratory failure. It is important to ensure that no other cause for the pulmonary hypertension can be identified. For example, a concomitant pulmonary arterial vasculopathy, such as seen in scleroderma or MCTD, should be sought, as specific therapy for the pulmonary arterial hypertension may be indicated in those circumstances.[148] In addition, common causes of pulmonary hypertension such as left-sided systolic or diastolic cardiac dysfunction may be present.[149] Right heart catheterization can distinguish between the various etiologies of pulmonary hypertension and is often required, as echocardiogram has limited sensitivity and specificity in this population.[147] Treatment with systemic pulmonary vasodilators has been controversial, as there is concern that such agents could worsen ventilation–perfusion matching in patients with group 3 pulmonary hypertension. However, a study assessing the inhaled vasodilator treprostinil found improvement in exercise capacity and no clinical worsening in the group that received inhaled treprostinil.[150]

■ Palliative Care

Symptom control is particularly important for patients with all stages of ILD. Pulmonary rehabilitation is encouraged to improve dyspnea in all symptomatic patients. The breathlessness due to advanced ILD may be treated with oxygen supplementation, low-dose opiates, and anxiolytics.[151] Chronic cough can be a debilitating symptom leading to social isolation, difficulty sleeping, and musculoskeletal pain. Low-dose opiates, oral corticosteroids, and more recently, neuromodulators such as pregabalin and gabapentin have been used with promising results.[152] Thalidomide also has been studied for the treatment of chronic cough in IPF with positive results, but widespread use is limited by side effect profile.[153] Evaluation for acid and nonacid reflux should be considered whenever intractable cough persists. In patients with advanced restrictive lung disease leading to hypercapnia, home noninvasive ventilation may be considered.

Palliative care services and hospice referral are appropriate for patients with advanced ILD to maintain a focus on the physical, psychological, and spiritual needs of both patients and their families.[154] Prognosis in ILD may be uncertain, depending upon the specific diagnosis, severity of disease, and trajectory of disease already demonstrated. Particularly in IPF, the likelihood of either progressive respiratory failure or acute decline due to exacerbation should be discussed. End-of-life discussions and advanced directives regarding mechanical ventilation should be broached.[154]

■ Lung Transplantation

Although lung transplantation (Chapter 106) has significant morbidity and mortality, it is an important and potentially life-extending alternative for patients with progressive fibrotic lung disease. Most patients with ILD referred for lung transplantation have IPF, and for those with advanced disease, survival after lung transplantation is superior to the natural history of their disease. Patients must have a strong social support system as well as the emotional and physical ability to tolerate a complex medical regimen of immunosuppressive therapy.[155]

The timing of listing is complicated in ILD, since the rate of progression is difficult to predict, and abrupt exacerbation of disease may occur. Patients who have undergone a complex workup at a lung transplantation center are assigned a lung allocation score, which is a numerical score that can be used to estimate each subjects' medical urgency and expected posttransplant survival rate relative to other patients on the waiting list for a lung transplant.[156,157] In general, a severely impaired $\mathrm{DL_{CO}}$ (<39%), continuous supplemental oxygen use, and advanced fibrosis on HRCT predict poor survival and are considered to be triggers for active listing.[76] Early referral to a lung transplant center is useful, as it allows full evaluation and education earlier in the disease course, as well as optimization of comorbidities.[158]

Advances in procedures such as ex vivo lung perfusion (EVLP), in which a pair of lungs is maintained outside the body so that a transplant team may thoroughly determine their viability, has allowed more subjects on the transplant wait list to receive organs.[159] Similarly, the use of extracorporeal membrane oxygenation (ECMO) for cardiopulmonary support has served as a bridge to transplantation in select patients with respiratory failure awaiting lung transplantation.[160,161]

CONCLUSION

The approach to ILD includes a careful history and physical examination, with a focus on identifying an etiology for the ILD. Important considerations include a complete investigation of environmental, occupational, and drug exposures as well as a thorough search for underlying connective tissue disease. Laboratory tests, pulmonary physiologic studies, radiography, and biopsy of lung tissue may be necessary. Multidisciplinary review is an essential part of the diagnostic evaluation. Decisions regarding diagnostic and therapeutic approach must be individualized.

CHAPTER 53

Systemic Sarcoidosis

Edward S. Chen

INTRODUCTION

Sarcoidosis is a systemic disorder characterized by noncaseating granulomatous inflammation at sites of disease.[1] Although any organ can be involved, the disease most commonly affects the lungs and intrathoracic lymph nodes. A diagnosis of sarcoidosis is most securely established by a compatible clinical presentation and laboratory and radiographic abnormalities, and is confirmed by a biopsy showing noncaseating epithelioid granulomas in more than one organ plus the exclusion of granulomatous disorders of known cause.[2] The disease results from the combined effects of genetic susceptibility and environmental exposures.[3] Disease-specific immune responses contribute to the nonnecrotizing granulomatous inflammation identified as sarcoidosis. The clinical course is highly variable according to clinical presentation and demographic features.[4] Corticosteroids remain the mainstay of treatment for patients with threatened organ failure or progressive disease. Long-term management must include a careful review of systems to identify symptoms that are not due to direct damage to tissues and organs and require alternative treatment strategies.

HISTORICAL PERSPECTIVE

The first descriptions of sarcoidosis originated in the late 1800s (Table 53-1). A series of letters and reports from Drs. Jonathan Hutchinson and Carl W. Boeck described patients who had characteristic skin lesions on their face and extremities, often referred to as Mortimer's malady, named after one of Hutchinson's patients. Several years later, Caesar Boeck (nephew of C.W. Boeck) recognized that these patients often had evidence of disease in multiple organs, such as regional lymph nodes in the neck and axilla, nasal and sinus passages, lung, and bones. The routine practice of biopsies and histopathology in the late 1800s confirmed the heterogeneity of sarcoidosis, causing granulomatous inflammation in different organs in different patients. The advent of radiography established that sarcoidosis most commonly affects the lungs.

The etiology of sarcoidosis has been ascribed to other diseases of contemporary historic interest due to overlapping clinical and histologic features. Cutaneous sarcoidosis was initially hypothesized to be a variant of lupus erythematosus, but later it was considered to be a variant of tuberculosis. Ansgar Kveim confirmed previous results reported by Williams and Nickerson, that an extract from sarcoidosis biopsy tissues caused granulomas to form 4 to 6 weeks following an intradermal injection in sarcoidosis patients.[5,6] The specificity of the Kveim reaction was evaluated by a large international case series summarized by Louis Siltzbach, in which >80% of sarcoidosis demonstrated a positive Kveim skin test, compared with <5% of patients with tuberculosis.[7] The challenges related to maintaining batch-to-batch consistency of Kveim reagent, and biosafety concerns related to the use of an extract from diseased tissues, abrogated the widespread operationalization of the Kveim skin test as a diagnostic tool.[8] More recently, the tools of cell and molecular biology have advanced our understanding of the immunologic, genetic, and etiologic basis of sarcoidosis but have not yet led to breakthroughs in the development of safe, effective therapies or cure.[3]

TABLE 53-1 Historic Sarcoidosis Discoveries and Eponyms

Descriptions of sarcoidosis by Jonathan Hutcherson (England) and Carl W. Beck (Norway) (late 1800s)	A series of letters described patients with a disease that caused characteristic skin lesions, often referred to as Mortimer's malady
Cutaneous sarcoidosis frequently presents with characteristic skin lesions on the face and scalp (1888)	Ernest Besnier (France) popularized "lupus pernio" as violaceous skin lesions of the nose, ear lobes, face, and scalp (initially hypothesized to be a variant of lupus erythematosus)
Sarcoidosis is a systemic disease—Caesar Boeck (Norway) and Jorgen Schaumann (Sweden) (early 1900s)	Advances in medical science usher the routine practice of obtaining biopsies and histopathology, characterize sarcoidosis as a systemic disease: granulomatous inflammation in the skin, lungs, eyes, bone, lymph nodes and spleen (hypothesized to be a variant of tuberculosis)
A causative agent for sarcoidosis is identified in diseased tissues	An extract prepared from sarcoidosis tissues results in granulomatous inflammation when injected into the skin of patients with sarcoidosis—Drs. Williams and Nickerson (United States, 1935) and Ansgar Kveim (Norway, 1941).
The Kveim reaction (positive skin test response) is specific to sarcoidosis	A large international case series using a standardized preparation of sarcoidosis spleen extracts demonstrates that a positive Kveim skin test is highly specific for sarcoidosis (>80% in sarcoidosis; <5% in tuberculosis); (Louis Siltzbach, 1960s)
Sarcoidosis frequently can present as an acute febrile illness, often with a good prognosis	First described in the early 1900s by Christian Heerfordt (Denmark) as a constellation of parotitis, fever, facial nerve palsy, and uveitis and later associated with sarcoidosis in the 1930's by Jan Waldenström (Sweden), now referred to as Heerfordt-Waldenström syndrome. Patients who initially present with bilateral hilar adenopathy, fever, polyarthritis, and erythema nodosum often can experience disease remission, later referred to as Löfgren syndrome (Sven Löfgren; 1940s).
Radiographic staging of pulmonary sarcoidosis	A system to categorize sarcoidosis chest x-ray findings proposed by Karl Wurm (Germany) and James Scadding (England) (1950s)
Pulmonary sarcoidosis results in granulomatous inflammation associated with a CD4+ lymphocytic alveolitis and expression of proinflammatory cytokines interferon γ (IFN-γ) and tumor necrosis factor (TNF)	Advances in medical science helped define the basic immunologic characteristics of sarcoidosis: granulomatous inflammation compartmentalized to the lung with heightened presence of CD4+ helper T lymphocytes (Th), increased expression of the Th1 cytokines IFN-γ and TNF

TABLE 53-2 Sarcoidosis Epidemiology and Genetic Associations

Sarcoidosis is found worldwide.
Worldwide, highest prevalence reported in Scandinavia; in the United States, highest prevalence in southeast coastal areas.
The peak age of onset is in middle-aged adults (40–55 years old), possibly bimodal (younger males vs. older females).
In the United States, the increased frequency and higher mortality are observed in Black Americans.
Higher prevalence among first-degree relatives of sarcoidosis probands and twin siblings.
The frequency of lupus pernio, Löfgren syndrome, cardiac involvement, and other clinical sarcoidosis manifestations is associated with race, ethnicity, and gender, supporting a genetic basis for this disease.
Genetic polymorphisms have been linked to disease risk and clinical phenotype, with the strongest associations identified within the HLA genes of the major histocompatibility complex (MHC) locus.

EPIDEMIOLOGY

Sarcoidosis is found worldwide, although accurate measurements of disease frequency are unknown because many people with sarcoidosis are asymptomatic, and there are neither sensitive nor specific diagnostic tests (Table 53-2). Traditionally, sarcoidosis was thought to have a peak onset during young adulthood. However, recent studies support that the peak age of onset ranges from 40 to 55 years old.[9] A longitudinal study from Japan found that the age at time of diagnosis steadily rose over their 40-year study period.[10] Although sarcoidosis was regarded a rare disease by some authorities,[11] the lifetime risk for developing sarcoidosis reported by developed countries is estimated to range from 1% to 3%. Based on autopsy studies, the prevalence of sarcoidosis is likely underestimated.

Recently, an actuarial study of a U.S. health insurance medial claims database reported the annual age-adjusted incidence was higher in Black Americans (17.8 cases per 100,000 per year) compared with white Americans (8.1 per 100,000),[12] and similar incidence rates have been reported by other countries in Europe, Asia, and Africa. A recent study using data from the Swedish National Patient Registry reported a prevalence of 160 sarcoidosis cases per 100,000 population.[13] Ireland and Italy are among several countries that have reported higher prevalence and geographic clustering of cases, implicating a contribution by environmental factors.[14,15] In the United States, the prevalence of sarcoidosis is highest in coastal areas of the southeastern states.[16]

The frequency of different clinical manifestations and outcomes of sarcoidosis also varies among geographic regions and ethnic groups and is influenced by gender. The prevalence of sarcoidosis in Sweden was reported to be higher in males than in females (179 vs. 141 cases per 100,000 population), and the incidence was higher in males with a lower median age at time of diagnosis (males 44.9 years vs. females 54 years).[13] Several studies report that women are diagnosed with sarcoidosis at an older age than men and the age distribution may be bimodal in some populations.[10,17,18] The results from two U.S. actuarial studies found that the risk for developing sarcoidosis is highest in Black American women compared with white American women or Black American men.[12,19] Additional studies of sarcoidosis in Black American women found that average annual incidence rate increased with age.[20,21]

Outcomes in sarcoidosis ascribed to race and gender may be influenced by other factors, including socioeconomic status, negatively affecting health care security due to disparities in health care access, trust in the medical care system, and adherence to therapy.[22,23] Future studies are needed to dissect the relative impact on these disparities on outcomes in sarcoidosis.

Whether a diagnosis of sarcoidosis is associated with increased mortality remains uncertain and may depend on the presence of comorbidities.[24] The presence of lung fibrosis, pulmonary hypertension, and older age have been associated with risk of mortality in patients with pulmonary sarcoidosis.[25,26] A recent study of a U.S. death certificate registry found that deaths attributed to sarcoidosis were significantly higher among Black Americans compared to white Americans.[27] A study of the Swedish National Patient Registry found that patients requiring treatment for sarcoidosis at the time of diagnosis had a twofold increased risk of death.[28] A recent U.S. cohort study found that sarcoidosis patients had higher rates of hospitalization compared with matched controls,[29] and a Swiss evaluation of a national healthcare database found that hospitalized sarcoidosis patients had significantly worse outcomes compared with matched controls, with longer length of stay and higher rates of in-hospital mortality and rehospitalization.[30] Taken together, sarcoidosis case rates and mortality appear to be rising, but prospective studies will be needed to determine if this is due to improved data collection or changes in risk factors or patient comorbidities.

GENETICS

Family and case-control studies provide strong evidence for a genetic influence on the risk of developing sarcoidosis and in determining clinical expression of the disease. Familial clustering of sarcoidosis has been estimated to involve 10% of cases, with a greater frequency among Black compared with white populations. The U.S. ACCESS (A Case Control Etiologic Study of Sarcoidosis) study found a higher relative risk of identifying sarcoidosis among siblings (odds ratio [OR], 5.8) or parents (OR, 3.8) of a sarcoidosis proband compared with that of the general population,[31] an observation supported by studies of twins.[32] The adjusted familial relative risk was estimated to be higher among whites in both the U.S. ACCESS study (relative risk [RR], ∼18) and in a U.K. study with mostly whites (RR, ∼36–73) and Blacks (RR, ∼2.8). Erythema nodosum is common in Scandinavian countries and Ireland but found in less than 5% of Black or Japanese patients. In contrast, lupus pernio appears more frequently among Black populations. In Japan, more than 50% of patients may have cardiac sarcoidosis.[17]

Genomic studies over the last two decades have provided insights into sarcoidosis disease presentation and prognosis.[33] Early studies using serologic and candidate gene techniques identified linkage disequilibrium with human leukocyte antigen (HLA) alleles. However, analyses using more advanced techniques have identified other genetic associations, most commonly with HLA class II and non-HLA genes within the major histocompatibility complex (MHC). The most notable example is the close association between HLA-DRB1*0301 (HLA-DR3), Löfgren syndrome, and disease resolution in northern European patients.[34] However, the results from analyses of non-Löfgren clinical presentations have been more variegated, identifying associations with both HLA class II and non-HLA genes within the major histocompatibility complex (MHC), as well as genes without known immunologic function.

More recently, multidisciplinary approaches to combine genomic and epidemiologic analyses have begun to shed light on how genetic factors modify risk for developing sarcoidosis associated with exposures such as cigarette smoke and insecticides.[35,36] The application of newer analytic techniques such as epigenetics, whole genome sequencing, and high-throughput computational methods for comparison of multimodal data (clinical, epidemiologic, proteomic, metabolomic) may help resolve the complex impact of genetic sarcoidosis risk factors.[37] The U.S. multicenter GRADS

TABLE 53-3 Sarcoidosis Immunopathology and Etiology

Sarcoidosis is identified by the presence of discrete, noncaseating, epithelioid granuloma.
Active sarcoidosis inflammation requires the presence of activated CD4+ T lymphocytes and is associated with local expression of the cytokines IFN-γ and TNF. • Potential contribution of Th17 immune responses • Reduced regulatory T-cell function
The oligoclonal expansion of αβ+ T cells compartmentalized to sites of disease is consistent with antigen-driven inflammation.
The utility of antifibrotic therapies for fibrotic sarcoidosis remains undefined.
Epidemiologic studies support positive (e.g., insecticides) and negative (e.g., cigarette smoke) environmental risk factors for developing sarcoidosis.
Certain classes of microbes (mycobacterial or propionibacterial organisms most implicated) are hypothesized to trigger sarcoidosis in genetically susceptible individuals, supporting a role for gene–environment interactions for the development of this disease. • Potential interactions with host microbiome
Serum amyloid A disaggregation within granulomas provides a mechanism for chronic disease.

study (Genomic Research in Alpha-1 Antitrypsin Deficiency and Sarcoidosis) represents the first large-scale integrative analysis of molecular, clinical, and environmental data in sarcoidosis patients.[38] A recent genome-wide transcriptome analysis of sarcoidosis BAL cells revealed genetic profiles that underscored associations between identified pathways known to be involved in sarcoidosis with pertinent sarcoidosis clinical features (Th1 and Th17 pathways with hilar lymphadenopathy, TGF-β and mTOR with parenchymal involvement, and IL7 + IL2 with airway involvement).[39]

PATHOGENESIS

Below we review key elements in the pathology and pathogenesis of sarcoidosis.

Histopathology

The pathologic hallmark of sarcoidosis is the presence of discrete, noncaseating, epithelioid cell granulomas (Table 53-3). The dominant cell in the central core is the epithelioid cell, thought to be a differentiated form of a mononuclear phagocyte (Fig. 53-1). CD4 lymphocytes and mature macrophages are typically interspersed throughout the epithelioid core, whereas both CD4+ and CD8+ T cells and B lymphocytes may be seen in the periphery of the granuloma. Occasionally, focal fibrinoid necrosis may be seen; necrosis should not be a dominant feature, and the presence of caseating necrosis must prompt an evaluation to exclude alternative

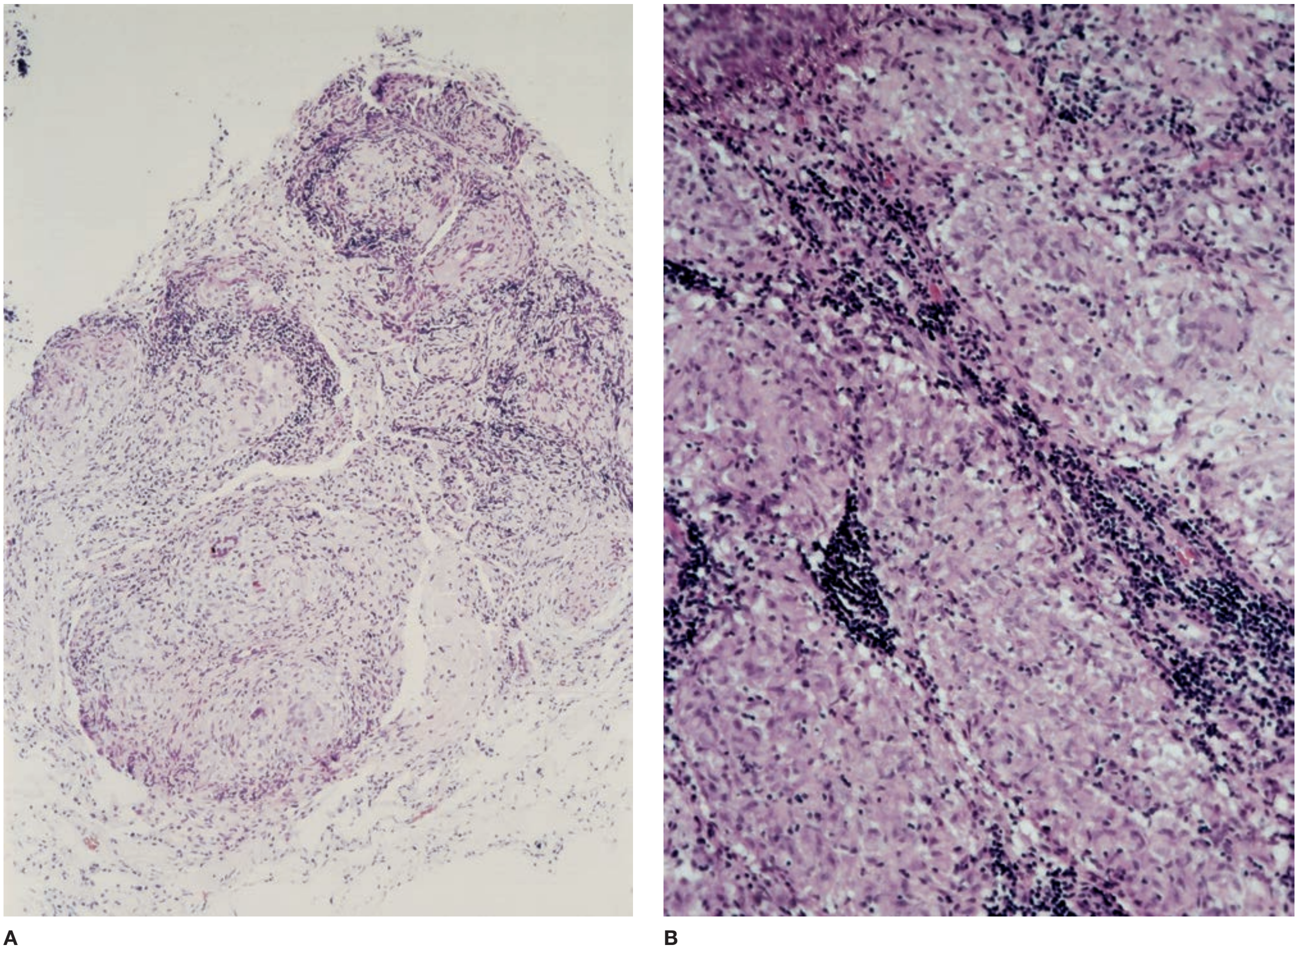

Figure 53-1 Photomicrographs of noncaseating granulomatous inflammation in sarcoidosis. **A.** Thoracoscopic lung biopsy showing extensive parenchymal involvement with granulomas, multinucleated giant cells, and mononuclear cell inflammation (×80). **B.** Mediastinal lymph node biopsy showing typical discrete epithelioid granulomas (×200).

diagnoses.[40] Additionally, the presence of organizing pneumonia and fibroblastic foci should prompt further investigation for other causes of lung injury and repair, including superimposed infection.[41,42] Giant cells, often containing cytoplasmic inclusions such as calcium- and iron-laden Schaumann bodies and Hamazaki–Wesenberg bodies, are scattered throughout the inflammatory locus. These features are not specific for sarcoidosis, as similar histopathologic findings can be seen in infections, berylliosis, Crohn disease, and local "sarcoid reactions" that occur near neoplastic, foreign body, or chronic inflammatory areas.[43]

In the lung, granulomas tend to form along perivascular, peribronchial, and septal regions, areas rich in lymphatic vessels. A mononuclear cell infiltration composed predominantly of lymphocytes is often present in the adjacent interstitium. Granulomas in sarcoidosis may resolve or undergo fibrosis, the earliest signs of which include circumferential collagen deposition, resulting in a stellate scar or hyalinized ghost of a former granuloma.

■ Immunopathology

Experimental models indicate that the first step in granuloma formation involves the tissue deposition of poorly soluble antigenic material. An initial innate immune response involves the recruitment and activation of antigen-presenting cells such as macrophages or dendritic cells expressing pattern recognition receptors and Toll-like receptors (TLRs). This results in the phagocytosis and degradation of antigenic proteins, generating peptide:MHC complexes that are displayed on the cell surface for analysis by CD4+ T cells (Fig. 53-2). The resulting adaptive immune response is characterized by the expression of effector cytokines dominated by a type 1 T helper cell (Th1; IFN-γ), Th2 (IL4/IL13), or Th17 (IL17/IL21/IL22) response, depending on the nature of the antigen and host genetic/epigenetic factors.[44] Active inflammation in sarcoidosis is strongly associated with the expression of Th1-promoting cytokines such as IL-12 and IL-18, and granuloma formation is supported by the subsequent effects of cytokines such as IFN-γ and TNF,[45] Th1-associated chemokines, and other mediators produced by activated innate and adaptive immune cells. Granulomatous inflammation is downregulated with clearance of antigen along with release of anti-inflammatory mediators such as transforming growth factor β (TGF-β) and IL-10 by local immune cells.[46,47]

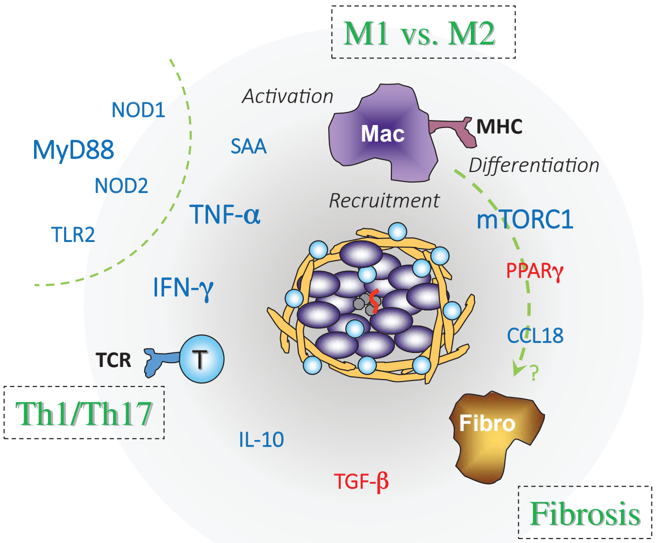

Figure 53-2 Concise model of sarcoidosis pathobiology. Granulomatous inflammation forms around an inflammatory nidus of poorly soluble antigen. Key receptors and mediators identified to be upregulated *(blue)* or downregulated *(red)* in sarcoidosis contribute to (1) localized synergistic induction of adaptive immune responses from a Th1-permissive cytokine environment; (2) initiation and maintenance of granulomatous inflammation through the activation, recruitment, and differentiation of macrophages; and (3) development of fibrosis through collagen deposition and recruitment and differentiation of fibroblasts and fibrocytes. *(Reproduced with permission from Chen ES. Innate immunity in sarcoidosis pathobiology. Curr Opin Pulm Med. 2016;22(5):469-475.)*

Sarcoidosis alveolar macrophages (AMs) express increased density of co-stimulatory molecules CD80, CD86, and CD40 consistent with their enhanced antigen-presenting capability; spontaneously produce TNF, IL-6, and IL1; and show increased activation of the transcription factor NF-κB and downregulation of the inflammation-suppressive transcription factor, peroxisome proliferator-activated receptor γ, consistent with classically activated M1 macrophages.[48,49] Other cytokines, IL-15, osteopontin, and the Th1-promoting cytokines IL-12 and IL-18 also are upregulated in sarcoidosis. Dendritic cells likely play a critical role in regulating local immune responses in sarcoidosis but have been the focus of few studies.[50,51] TNF is a key effector cytokine (therefore a therapeutic target) driving granuloma formation in sarcoidosis, as enhanced release of TNF by BAL cells is associated with persistent disease.[52] A recent study demonstrated that activation of the metabolic checkpoint kinase mTORC1 results in macrophage aggregation, hypertrophy, and proliferation resembling granulomatous inflammation in experimental models, suggesting a role in sarcoidosis.[53,54] The formation of granulomas in sarcoidosis is driven by the activation, recruitment, and differentiation of macrophages, a focus of ongoing active research (Fig. 53-2).[55]

Lymphocytes play a pivotal role in directing the inflammation in sarcoidosis. Studies of patients with immunodeficiency syndromes including untreated HIV infection demonstrate that sarcoidosis does not occur in the absence of functional CD4+ T cells, and that HIV+ patients who have a prior history of sarcoidosis can experience recrudescence of sarcoidosis upon effective treatment of HIV as part of an immune reconstitution syndrome.[56,57] Early studies identified that T lymphocytes recruited to the lung, skin (Kveim biopsy sites), and other sites of active sarcoidosis display a limited number of αβ+ T-cell receptor sequences, suggesting that sarcoidosis involves an antigen-specific response.[58–60] The best-studied example involves the remarkable expansion of Vα2.3 (AV2S3)+ BAL T cells from HLA-DRB1*0301-positive Scandinavian patients with sarcoidosis.[61] The specific antigens driving these clonally expanded T-cell populations remain uncertain but may include autoantigens such as vimentin and microbial antigens such as mKatG.[62,63]

■ Th1 and Th17 Immunity

Multiple studies confirm that pulmonary sarcoidosis is associated with enhanced expression of IFN-γ, IL-12, and IL-18 but low or undetectable levels of IL-4 or IL-5, indicating a dominant type 1 (Th1) immune response compartmentalized to the lung and other sites of inflammation.[64] Enhanced expression of IFN-γ by CD4+ T cells is one of the oldest and enduring observations in sarcoidosis. Perhaps most intriguing is the recent identification that the majority of IFN-γ-expressing CD4+ T cells in the sarcoidosis lung bear a Th17 surface phenotype,[65] supporting a hypothesis that proinflammatory Th17 cells contribute to sarcoidosis through their ability to migrate to sites of disease and functionally transform into nonclassic Th1 cells induced by the local cytokine environment enriched in Th1-promoting IL-12 and TNF.[66] Despite an established role for Th17 effector T cells in granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) and tuberculosis,[67,68] it is unknown whether Th17 responses play a critical role in disease outcome or can substitute for the polarized Th1 responses documented in sarcoidosis.[69]

Reduced Treg Functional Capacity

Regulatory T cells (Tregs) maintain immune homeostasis by suppressing the function of antigen-presenting cells and effector T cells. Several groups have reported that FoxP3-positive natural Tregs (nTreg) accumulate at sites of granulomatous inflammation in sarcoidosis but may have reduced function in suppressing proinflammatory cytokine expression and granuloma formation.[70–72] Reduced Treg survival and enhanced apoptosis of Tregs may contribute to insufficient immunoregulatory function in sarcoidosis.[73] Diminished numbers of immunoregulatory natural killer T (NKT) cells have also been reported and may contribute to chronic active sarcoidosis.[74] Whether the functional impairment of nTreg or NKT cells in sarcoidosis is a primary defect or secondary to the hyperimmune Th1/Th17 responses in sarcoidosis remains uncertain.[75] One group studied the effects of nebulized vasoactive intestinal peptide (VIP) in sarcoidosis and found it significantly increased number and inhibitory function of lung CD4+CD127-CD25+ Tregs and reduced TNF production by BAL cells,[76] suggesting a potential treatment for immune-mediated lung diseases including sarcoidosis.

Role of Innate Immunity

The immunopathology of sarcoidosis can be modeled in this experimental context. Sites of granulomatous inflammation such as the lung contain activated T cells and mononuclear phagocytes that express the same proinflammatory cytokines and chemokines that have been shown experimentally to be critical in granuloma formation.[18] Active pulmonary sarcoidosis is associated with a lymphocytic alveolitis associated with CD4+CD45RO+CCR7- effector memory T cells. CD4+ T cells in sarcoidosis spontaneously produce IFN-γ and other cytokines, including TNF, and the coexpression of IFN-γ and TNF by "multifunctional" T cells has been linked to clinical outcomes, such as in patients with Löfgren syndrome who have higher rates of disease remission.[63]

Given the lack of evidence for an active mycobacterial or other viable microbial infection in sarcoidosis tissues at any point in the disease and often in the context of long-term treatment with immunosuppressive medications, another major challenge is to understand what drives chronic granulomatous inflammation in sarcoidosis. Since mycobacterial antigens (mKatG, ESAT-6) represent candidate pathogenic antigens that provoke adaptive responses in subsets of patients with sarcoidosis,[77,78] examining the events following exposure to mycobacteria may identify innate host defense pathways that contribute to the pathology of sarcoidosis.

Studies have demonstrated increased expression of genes related to the TLR2 innate signaling pathway in peripheral blood mononuclear cells (PBMCs) 24 h after incubation with *M. tuberculosis*,[79] complementing other studies that have associated polymorphisms in TLR2 with susceptibility to mycobacterial infection. Enhanced responsiveness to TLR2 stimulation, including enhanced induction of TNF, has been observed in blood and lung cells from sarcoidosis patients.[80–82] In this context, serum amyloid A (SAA) has been identified as an innate ligand expressed in sarcoidosis tissues that can induce the expression of proinflammatory cytokines including TNF, in part, through TLR2[80] (Fig. 53-3). Interestingly, TLR2 expression on respiratory epithelial cells is induced by TNF and IFN-γ, potentially resulting in a positive feedback loop in the

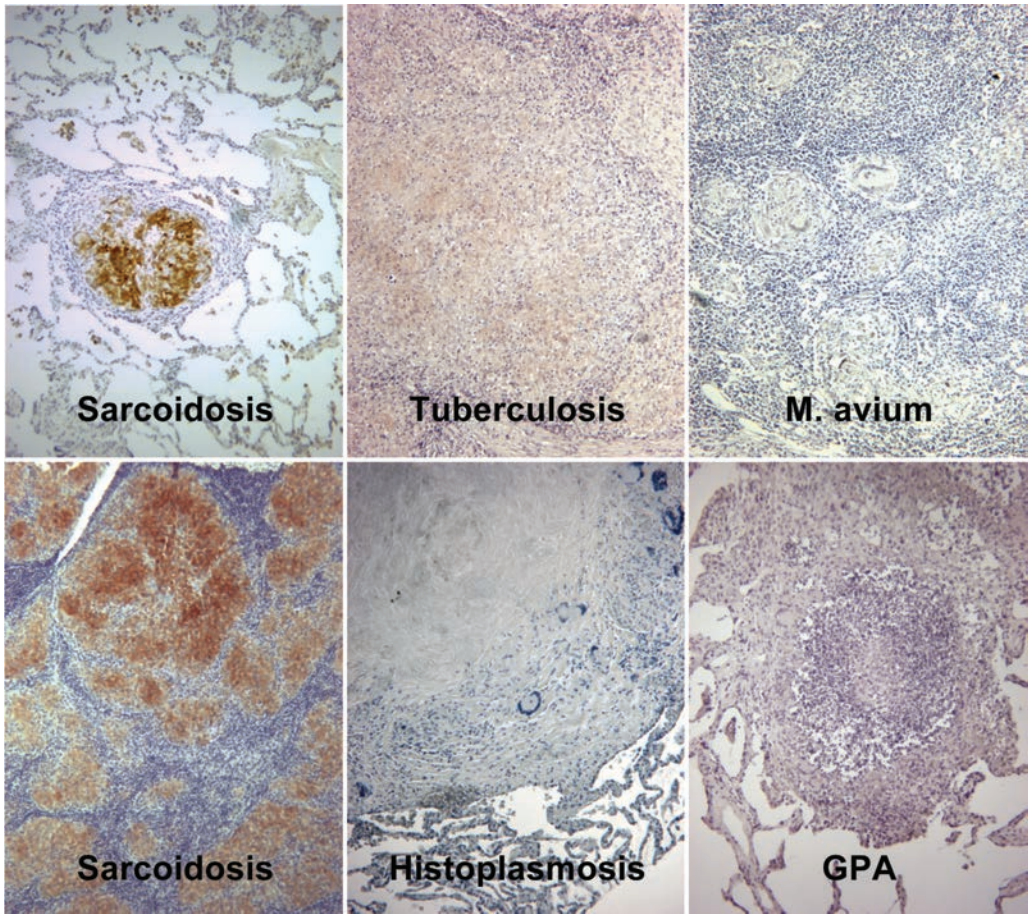

Figure 53-3 Immunohistochemistry showing focal deposition of serum amyloid A (SAA) *(brownish stain)* in tissues from patients with sarcoidosis but little or no staining for SAA in tuberculosis, *Mycobacterium avium* infection, histoplasmosis, or granulomatosis with polyangiitis (GPA).

setting of granulomatous inflammation, an effect that is enhanced by corticosteroids.[83] Aberrant TLR2 function may also play a role in anergy in sarcoidosis, an effect that can be modified by nicotine,[84] a potential clue regarding the interaction between smoking and sarcoidosis.

Mutations in the nucleotide-binding oligomerization domain 2 (NOD2) pathway have been linked with Blau syndrome, an autosomal dominant disorder causing granulomatous inflammation of the skin, eyes, and joints. NOD2 mutations have also been identified as risk factors for Crohn disease, a granulomatous inflammatory bowel disease. More recently, NOD2 has also been linked to early onset sarcoidosis in children, but this linkage has not been established in adult sarcoidosis.[85] A related study identified NOD1 stimulation as another innate pathway that contributes to heightened immune responsiveness in sarcoidosis via enhanced production of TNF and IL-12 by BAL cells.[86] A denominator for these observations is the myeloid differentiation primary response gene (MyD88), which serves as an innate immune signal transduction adaptor downstream of all NOD-like receptors, and all TLRs (except TLR 3). Of interest, polymorphisms of the MyD88 gene have been associated with risk for developing sarcoidosis.[87] While sarcoidosis is not a manifestation of an active infection, microbial proteins are a rich source of ligands to innate receptors, offering a link between exposure to microbes (e.g., previously contained, and eradicated infection) and sarcoidosis.[88]

■ Lung Fibrosis in Sarcoidosis

The mechanisms that promote pulmonary fibrosis in sarcoidosis remain uncertain. IFN-γ has direct antifibrotic effects,[89] but this pleotropic cytokine may mediate fibrosis by enhancing lung injury.[90] There is evidence that sarcoidosis AMs can transition to an alternative profibrotic M2-like phenotype,[91] which can promote lung fibrosis in pulmonary sarcoidosis through the expression of chemokines such as CCL18.[92] The lack of evidence for IL4 upregulation in sarcoidosis suggests that IL-10 or IL-13 may foster this profibrotic macrophage phenotype.[93] Sarcoidosis is associated with diminished expression of PPARγ,[49] and whether this contributes to macrophage differentiation in sarcoidosis requires further study.[94]

Increased expression of TGF-β, fibronectin, insulin-like growth factorb1 (IGF-1), laminin, and matrix metalloproteases by sarcoidosis AMs may promote a fibrosis-permissive environment in chronic active sarcoidosis through the recruitment and activation of fibroblasts (Fig. 53-2).[64] While increased TGF-β is associated with the presence of structural lung disease among sarcoidosis patients,[95] the exact role of TGF-β in sarcoidosis remains unclear since it has not only profibrotic but immunoregulatory effects.

Irreversible lung scarring can result in sarcoidosis, most commonly observed in patients with chronic active pulmonary sarcoidosis.[96] Using an animal model, repeated administration of SAA maintained experimental granulomatous inflammation, providing a possible mechanism for sustaining ongoing inflammation in sarcoidosis.[80] SAA deposition in sarcoidosis tissues correlates with local collagen deposition,[80] and a recent study of blood SAA levels found that patients with fibrotic sarcoidosis had higher SAA levels compared to sarcoidosis without lung fibrosis, suggesting this may be a marker of more severe disease.[97]

Presumably, untreated (or insufficiently treated) sarcoidosis causes lung injury with resultant scarring as part of a local healing response. Patients with fibrotic sarcoidosis are at risk for complications from bronchiectasis, mycetoma, and hemoptysis. Whether lung fibrosis associated with sarcoidosis involves abnormal fibroblast activity akin to idiopathic pulmonary fibrosis remains uncertain, and studies are needed to demonstrate whether antifibrotic therapies have a role in sarcoidosis.[98]

■ ETIOLOGY

The cause of sarcoidosis remains uncertain. While genetic factors may permit a disease such as sarcoidosis to occur, the challenge is to understand what stimulates the immune system to cause granulomatous inflammation identified as sarcoidosis. Seasonal variation in case rates and time-space clustering of cases support a hypothesis that environmental exposures are linked to sarcoidosis.[99,100] Occupation-linked risks have been described in healthcare professionals, firefighters, workers involved in the lumber industry, and military personnel,[101] and these associations are supported by a recent study using advanced high-throughput technologies.[102] Chronic beryllium disease causes a granulomatous pneumonitis histologically identical to pulmonary sarcoidosis in less than 5% of exposed workers following immunologic sensitization to beryllium.[103] Exposures to silicates and immune-sensitizing metals also can cause granulomatous inflammation.[104] The high incidence of respiratory illnesses following the 9/11 World Trade Center disaster among first-response rescue workers identified a time-space clustering of a “sarcoidosis-like” pulmonary disease.[105] However, two studies of surgical lung biopsies obtained from WTC-exposed responders and residents suggest that in most instances the pulmonary disease from WTC exposure is consistent with complex dust exposure rather than sarcoidosis.[106,107] A minority of WTC-exposed responders developed multisystem disease, supporting a likely diagnosis of multisystem sarcoidosis.[108] Collectively, these observations support the hypothesis that environmental exposures are an important source of stimuli that can trigger sarcoidosis and other inflammatory responses in susceptible hosts.

The U.S.–based multicenter study of sarcoidosis etiology, ACCESS, compared 706 newly diagnosed, biopsy-proven sarcoidosis cases with age-, sex-, and race-matched controls.[109] Results from the study did not identify any environmental or occupational associations with risk for developing sarcoidosis that met the study’s design goals of odds ratio (OR) greater than 2.0 and an exposure prevalence of greater than 5%.[110] Weak positive associations (OR, ~1.5) were found for insecticide use at work, mold/mildew exposures at work, and musty odors, suggesting possible links to microbial-rich environments. Sarcoidosis was not associated with exposure to heavy metals including beryllium, wood dusts, or rural residence as previously hypothesized. The ACCESS study found a robust negative association of smoking and sarcoidosis risk, confirming earlier studies. The lack of a single, dominant exposure associated with sarcoidosis risk supports the concept that gene–environment interactions are important in causing this disease.

Since sarcoidosis was first described, investigators have postulated an infectious cause of the disease based on the clinical and histologic similarities to tuberculosis.[111] A meta-analysis of studies published between 1980 and 2006 identified a 10- to 20-fold greater likelihood of detecting mycobacterial nucleic acids (DNA, RNA) in sarcoidosis tissues than control tissues.[112] Several groups have demonstrated that as many as 70% of sarcoidosis patients have lung and blood T-cell responses to mycobacterial antigens including mKatG, *Mycobacterium tuberculosis* ESAT-6, Ag85, and superoxide dismutase.[113–115] Along these lines, other studies identified extensive overlap in peripheral blood gene expression between individuals with sarcoidosis and tuberculosis infection.[116–118]

Japanese investigators found *Propionibacterium acnes* DNA in 80% to 98% of sarcoidosis tissues from Japan and Europe but also in 0% to 60% of control tissues.[119] However, a role for *Propionibacterium* (now reclassified as *Cutibacterium*) in sarcoidosis remains unclear because of the frequent detection of these organisms from non-sarcoidosis tissues and frequent observation of immune responses to these organisms in non-sarcoidosis control individuals.[120]

Despite the evidence linking some microbes to sarcoidosis etiology, a recent phase 2 study found that 8 weeks of antimycobacterial therapy did not result in any clinical improvement in patients with pulmonary sarcoidosis.[121] This confirms that active sarcoidosis is not caused by the presence of viable mycobacterial organisms (or other infectious microbes) in affected tissues; rather investigators favor the hypothesis that antigens originating from certain classes of microbial organisms (exposures to microbes that were eradicated by an effective host immune response) can trigger sarcoidosis in those with genetic susceptibility. However, there is growing concern that host–microbiome interactions modulate inflammation in systemic illnesses,[122] including sarcoidosis,[88,123] potentially modified by antimicrobial agents, and future studies are needed to reassess the effects of antimicrobial agents in this context.

Other microbial agents such as *Borrelia burgdorferi*, *Chlamydia pneumoniae*, or *Rickettsia helvetica* have been implicated in sarcoidosis from tissue or serologic studies, but these latter studies all lack wider confirmation. High titers of antibodies against lymphotropic DNA viruses (Epstein-Barr virus, cytomegalovirus, and human herpesvirus type 6) and HTLV1 have been described in patients with sarcoidosis but may reflect generalized B-cell activation in sarcoidosis, since a viral origin has not been substantiated by viral cultures or tissue analysis.

Some investigators hypothesize an etiologic association with autoimmunity, perhaps triggered by an infectious agent through molecular mimicry. In support of this concept, sarcoidosis is associated with features of autoimmunity, such as antinuclear antibodies, rheumatoid factor, hypergammaglobulinemia, and immune complexes. Sarcoidosis patients often express low-titer autoantibodies of unclear significance, although no disease-specific autoantibody profile has been identified. One recent study identified several potential autoantigens such as vimentin, ATP synthase, and lysyl-tRNA whose derived peptides stimulated Th1 lymphocytes in the blood or lung of sarcoidosis patients, suggesting these responses may help sustain chronic inflammation.[124]

CLINICAL FEATURES

The clinical features of sarcoidosis are discussed in detail below.

■ Classification

The clinical manifestations and course of sarcoidosis vary greatly (Table 53-4). Although any organ of the body can be affected, the lungs or intrathoracic lymph nodes are involved in more than 90% of patients with sarcoidosis. Patients may present with no symptoms or develop acute, subacute, or indolent manifestations. Systemic constitutional symptoms such as fever, fatigue, malaise, and weight loss are seen in more than 50% of patients and may be disabling. One classification scheme with prognostic information categorizes patients based on their initial manifestations as follows:

TABLE 53-4 Clinical Manifestations of Sarcoidosis

Organ System (Percent Clinical Disease)	Major/Common Manifestations
Pulmonary (>90%)	Restrictive, obstructive impairment, reduced diffusing capacity, fibrocystic disease, pulmonary hypertension, bronchiectasis, cavitating nodules, mycetomas, lobar atelectasis, tracheal or bronchial stenosis, superior vena cava syndrome, pleural disease, pneumothorax
Constitutional symptoms (>50%)	Fevers, night sweats, malaise, excessive fatigue, unintentional weight loss
Upper respiratory tract and oral cavity (5%–10%)	Hoarseness, laryngeal or tracheal obstruction, nasal congestion, sinusitis, saddle nose deformity, upper airway obstruction, sleep apnea, dacryoadenitis
Skin (20%–30%)	Chronic nodules and plaques, lupus pernio, alopecia, subcutaneous sarcoidosis, ichthyosis, alopecia, scar granulomas, tattoo granulomas, erythema nodosum (a nonspecific, nongranulomatous panniculitis)
Ocular (20%–30%)	Anterior and posterior uveitis, chorioretinitis, conjunctivitis, optic neuritis, granulomatous orbital inflammation
Cardiac (5%–20%)	Arrhythmias, heart block, cardiomyopathy, sudden death, pericardial disease, valvular disease, ventricular or atrial mass
Neurologic (5%–10%)	Facial and other cranial neuropathies (e.g., Bell's palsy), basilar leptomeningitis, encephalitis, aseptic meningitis, brain mass, seizures, hydrocephalus, pseudotumor cerebri, hypothalamic hypopituitarism, optic chiasmal involvement, Horner's syndrome, Argyll Robertson or Adie's pupil, cerebritis (white matter involvement), corpus callosum involvement, brain stem involvement, cerebellar involvement, cerebral vascular occlusion, myelopathy, transverse myelitis, intraspinal mass, cauda equina or spinal root involvement, peripheral neuropathy, mononeuritis multiplex, polyneuropathy, small fiber neuropathy
Hepatic/abdominal (10%–20%)	Hepatomegaly, jaundice, cirrhosis, abdominal/retroperitoneal lymphadenopathy, jaundice with pruritus, cirrhosis with portal hypertension, splenomegaly, pancreatic mass, dysmotility involving esophagus/small or large intestine, peritoneal implants, appendicitis
Hematologic (20%–30%)	Peripheral or retroperitoneal lymphadenopathy, splenomegaly, hypersplenism, anemia, lymphopenia, hypergammaglobulinemia, lymphedema, idiopathic thrombocytopenic purpura (ITP)
Joints and musculoskeletal (10%–20%)	Arthralgia, polyarthritis, Achilles tendinitis, heel pain, dactylitis, bone cysts, myopathy
Exocrine gland (10%–20%)	Salivary, lacrimal, and parotid gland enlargement, sicca syndrome/Heerfordt syndrome, parotid mass
Endocrine (10%–20%)	Hypercalciuria, hypercalcemia, hypopituitarism, diabetes insipidus, thyroid mass, thyroiditis
Renal (<10%)	Renal calculi, nephrocalcinosis, renal failure, interstitial nephritis, leukocyturia, microhematuria
Genitourinary (<5%)	Ovarian or uterine mass, dysmenorrhea, testicular mass, epididymitis/uterine mass, ovarian involvement, menometrorrhagia, testicular mass, epididymitis, intermittent azoospermia
Psychosocial manifestations (30%–60%)	Depression, anxiety, fatigue

(1) asymptomatic; (2) acute sarcoidosis with or without erythema nodosum; (3) sarcoidosis with symptoms or signs of pulmonary disease for less than 2 years; (4) chronic pulmonary sarcoidosis of more than 2 years; and (5) dominant extrapulmonary sarcoidosis. Two years represents an arbitrary but useful reference point for distinguishing patients who usually, but not always, have long-term disease.

Rare manifestations of sarcoidosis include unusual patterns of organ involvement, the result of granulomatous inflammation developing in unusual locations for sarcoidosis, or when sarcoidosis is associated with a second disorder. In general, rarer manifestations reflect the known pathophysiology and clinical behavior of more common organ involvement.

Asymptomatic Sarcoidosis

Up to two-thirds of patients are asymptomatic but have sarcoidosis diagnosed after an incidental radiographic finding of bilateral hilar adenopathy. Occasionally, interstitial infiltrates are seen in association with intrathoracic adenopathy in asymptomatic patients, most commonly in whites.

Acute Sarcoidosis with or without Erythema Nodosum

Sarcoidosis may manifest with the acute onset of erythema nodosum associated with bilateral hilar adenopathy, fevers, polyarthritis, and often uveitis, known as Löfgren syndrome. Erythema nodosum is characterized by tender reddish nodules several centimeters in diameter, usually located on the lower extremities; histologic examination shows panniculitis, not granulomas. The polyarthritis is often severe and incapacitating, typically involving the ankles, feet, knees, and, occasionally, wrists and elbows. Approximately 10% of patients with this syndrome have a normal chest radiograph. Löfgren syndrome is more common in European and white populations but found in less than 5% of Blacks with sarcoidosis. Some patients manifest acute arthritis, bilateral hilar lymphadenopathy, and constitutional symptoms without erythema nodosum. In either case, the prognosis is excellent for remission in 70% to 80% of patients, typically within several months.

Pulmonary Sarcoidosis

Respiratory symptoms occur in 40% to 60% of patients.[125] The most common symptoms are cough and shortness of breath, usually of a progressive, insidious nature. The cough is usually nonproductive and may be severe. Dyspnea is typically worse with exertion. Sputum production and hemoptysis are frequent in patients with fibrocystic sarcoidosis that is often associated with bronchiectasis. Ill-defined chest pain is a frequent complaint, possibly caused by nerve irritation from inflammation, scarring, or lymph node enlargement in the chest. Chest tightness and wheezing are common with endobronchial disease or fibrocystic changes. These symptoms are usually poorly responsive to bronchodilators, except in those with reversible airway hyperreactivity. Physical findings are infrequent, with lung crackles heard in less than 20% of patients; clubbing is rare.

Chest Imaging

The chest radiograph is abnormal in more than 90% of known cases and carries prognostic information.[126] Chest radiographs are categorized by international convention: stage 0 (<15%) denotes a normal chest x-ray; stage I (30% to 50%) shows symmetric bilateral hilar adenopathy often with right paratracheal adenopathy; stage II (40% to 60%) and stage III (10% to 20%) indicate the presence of pulmonary infiltrates with (stage II) or without (stage III) bilateral hilar adenopathy; stage IV (<15%) shows obvious scarring with fibrocystic changes with cephalad hilar retraction (Fig. 53-4). The hilar adenopathy often has a symmetric "potato node" appearance and calcifications are uncommon. Infiltrates most commonly appear as linear or reticulonodular markings in the middle and upper lung fields, but occasionally can present with patchy, focal alveolar consolidations mimicking infectious pneumonia, granulomatosis with polyangiitis (GPA), eosinophilic pneumonia, or malignancy. Less frequently, a miliary pattern is observed but would warrant exclusion of tuberculosis, hypersensitivity pneumonitis, chronic beryllium disease, or lymphangitic carcinomatosis. While stage IV sarcoidosis is associated with a poor prognosis,[127] the recent ACCESS study affirms the weak correlation between stages I, II, or III chest radiographs and clinical status.[128] Mycetomas often represent a complication of fibrocystic stage IV sarcoidosis.[129] Unusual radiographic signs of sarcoidosis include pneumothorax, isolated nodule or mass, lobar atelectasis, or pleural effusions.

Chest computed tomography (CT) typically demonstrates that infiltrates tend to be central, following bronchovascular structures.[130] Ground-glass infiltrates or honeycombing also can be seen. The adenopathy of sarcoidosis typically appears as multiple discrete enlarged lymph nodes rather than amorphous, mass-like growths more suggestive of malignancy. CT of the chest is often useful in the evaluation of patients with suspected sarcoidosis and to help plan bronchoscopic biopsy of enlarged lymph nodes, define unusual radiographic features, fibrocystic disease, or bronchiectasis.

Pulmonary Function Tests

Pulmonary function may be normal even when the chest radiograph demonstrates pulmonary infiltrates. However, restrictive impairment with reduction in lung volumes, forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1), is common, particularly when pulmonary infiltrates are present on chest radiograph. Reduction in diffusing capacity can be seen in association with restrictive impairment or as an isolated deficit, the latter raising concern for concomitant pulmonary hypertension.[131] Obstructive impairment is as common as restrictive impairment, particularly in advanced fibrocystic disease or endobronchial disease.[132] A subgroup of patients has bronchial hyperresponsiveness and airway obstruction that may respond to bronchodilators. Resting hypoxemia and exercise O_2 desaturation are typical when there is severe obstructive or restrictive impairment. CO_2 retention is unusual except in advanced pulmonary disease.

Pulmonary Hypertension

Pulmonary hypertension represents an important complicating factor of pulmonary sarcoidosis because it is associated with increased mortality. The prevalence of pulmonary hypertension is estimated to be 6% to 20% among patients with sarcoidosis, with highest rates (~75%) observed in patients with advanced lung disease awaiting lung transplant.[133] In patients with dyspnea disproportionate to pulmonary function impairment, pulmonary hypertension may be seen in 50% of cases.[134] The causes of pulmonary hypertension include extensive interstitial lung disease with loss of pulmonary capillary bed, granulomatous pulmonary vasculitis, pulmonary arterial impingement by lymphadenopathy or traction lung scarring of bronchovascular bundles, left heart dysfunction, or rarely, pulmonary venous occlusion.[135] Patients typically present with progressive dyspnea. Echocardiography is a useful screening technique, but right heart catheterization is needed to confirm clinically significant pulmonary hypertension.

A single-center longitudinal study of patients with severe sarcoidosis-associated pulmonary hypertension (SAPH) (mean pulmonary artery pressure [mPAP] >35 mm Hg *or* mPAP 25–35 with cardiac index <2.5 L/min/m^2) over a median follow-up period of 28 months reported that 40% either died or underwent lung transplantation.[136] Treatment with medications to treat pulmonary hypertension did not result in significant differences in outcomes, despite improvement in hemodynamic profiles. Treatment with immunosuppression medications improved hemodynamic profiles in select cases.

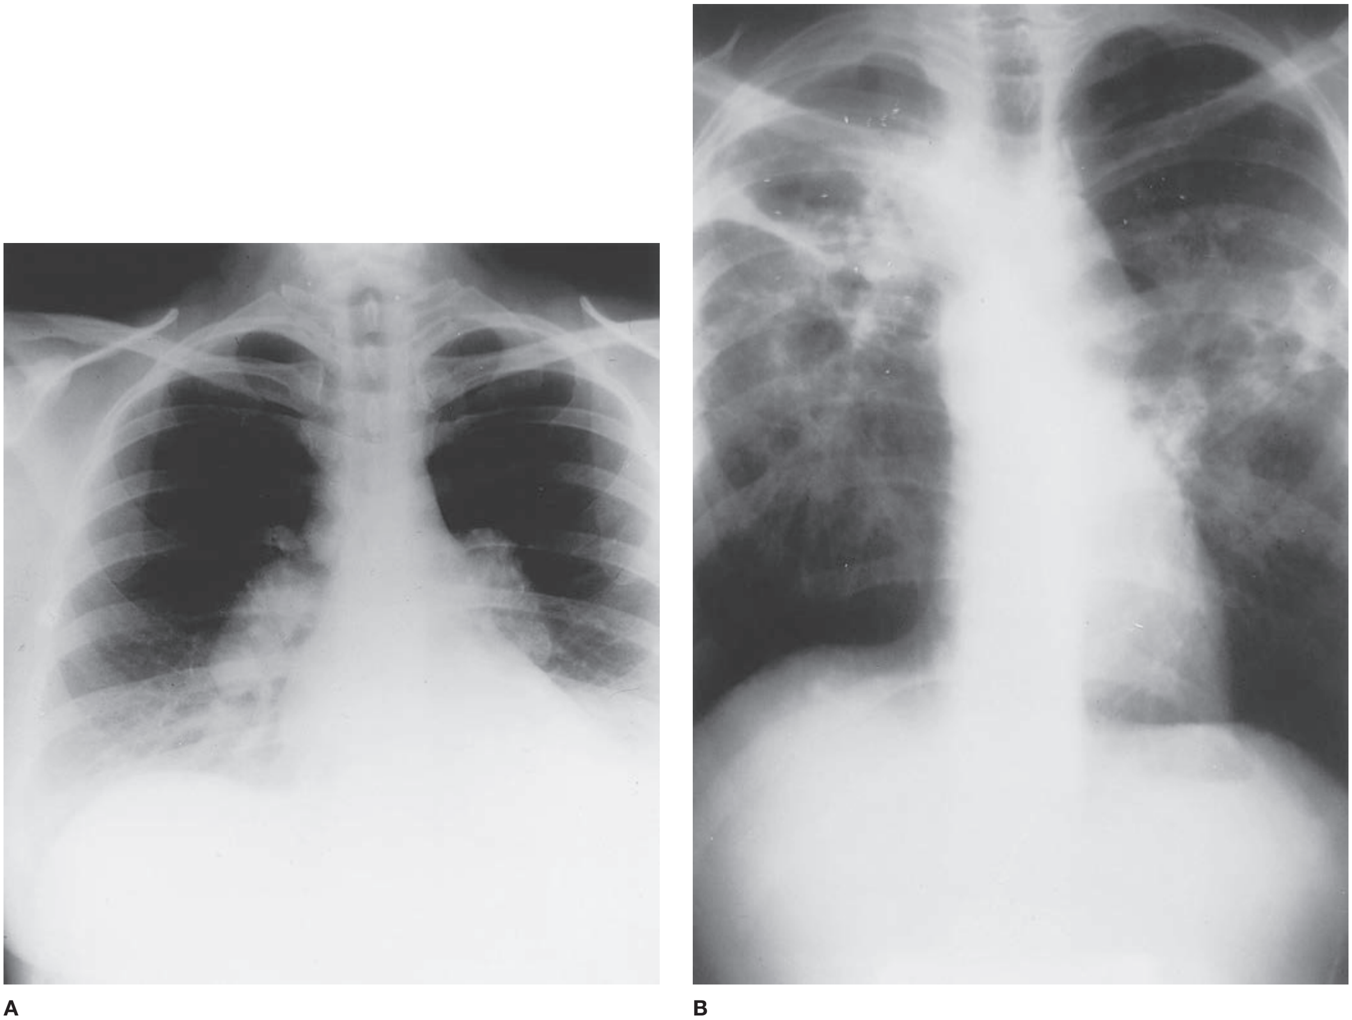

Figure 53-4 Chest radiographs of pulmonary sarcoidosis. **A.** Stage II sarcoidosis pattern with prominent, discrete "stand-away" hilar nodes, right paratracheal adenopathy, and fine reticulonodular infiltrates. **B.** Fibrocystic sarcoidosis with extensive mid and upper lung scarring, bullous and cystic changes, hilar retraction, and parenchymal infiltrates.

The results from an international Registry for SAPH (ReSAPH) reported a 5-year transplant-free survival of 62% among patients with precapillary pulmonary hypertension (mPAP ≥25 mm Hg), with reduced diffusing capacity (<35% predicted) and low 6-min walk distance (<300 m) identified as risk factors for reduced transplant-free survival.[137] Recent revisions to the definition of pulmonary hypertension warrant reassessment of the long-term effects of less severe pulmonary hypertension associated with sarcoidosis.[138]

Necrotizing Sarcoid Granulomatosis

This disorder is characterized by large, confluent, noncaseating granulomas involving both pulmonary arteries and veins but without systemic vasculitis and is often considered a variant of pulmonary sarcoidosis.[139,140] Patients may be asymptomatic or have cough, dyspnea, fever, chest pain, or constitutional symptoms. Chest radiographs typically demonstrate multiple, usually noncavitating nodules. Pleural disease with pleurisy or pleural effusions occurs in the majority of patients with this variant and may be a clue to the diagnosis. Most patients have spontaneous improvement or a rapid response to corticosteroid therapy.

■ Extrapulmonary Sarcoidosis

Many patients have manifestations of granulomatous inflammation in one or more organ systems either in addition to pulmonary involvement or without evidence of pulmonary disease (Table 53-4). The presence of these characteristic extrapulmonary manifestations may help distinguish sarcoidosis from other systemic diseases. Defining clinically significant organ involvement remains a challenge despite improved imaging techniques.

Sarcoidosis of the Upper Respiratory Tract and Oral Cavity

Sarcoidosis of the upper respiratory tract (SURT) occurs in 5% to 10% of patients, usually involving the nasal sinuses or laryngeal structures. Symptoms of nasal congestion, sinusitis, and intermittent epistaxis are often chronic and unresponsive to decongestants or topical corticosteroids. Chronic disease or surgical intervention may result in destruction of the nasal septum and a "saddle nose" deformity. Laryngeal sarcoidosis may manifest with severe hoarseness, stridor, or acute respiratory failure secondary to upper airway obstruction. Frequently, laryngeal sarcoidosis is associated with chronic skin lesions, lupus pernio, or sinus disease. Oral and pharyngeal sarcoidosis is rare but may manifest with macroglossia, tongue mass, or palatal mass with cartilaginous or bone destruction.

Cutaneous Sarcoidosis

Chronic skin sarcoidosis is seen in 20% to 30% of patients, usually manifesting as plaques or subcutaneous nodules, and is more common and severe in Blacks.[141] Typically, the plaques are located around the hairline, eyelids, ears, nose, and extensor surfaces of the arms and legs. Lupus pernio is a disfiguring form of cutaneous sarcoidosis of the face, with violaceous plaques and nodules covering the nose, nasal alae, malar areas, and areas around the eyes. Erythema nodosum is a non-granulomatous panniculitis seen in acute sarcoidosis.

Ocular Sarcoidosis

Ocular involvement is detected in approximately 20% to 30% of patients.[142] In the ACCESS study, 12% of patients had ocular manifestations as a presenting symptom.[109] Age, ethnicity, and gender may influence risk of ocular sarcoidosis; compared to white Americans, Black Americans present more frequently with this manifestation at a younger age.[143]

Uveitis is the most common ocular manifestation and is often associated with bilateral hilar adenopathy. The uveitis is more commonly anterior, and may be unilateral or bilateral, with either granulomatous or nongranulomatous features. Granulomatous conjunctivitis is less common. Optic neuritis, or severe chorioretinitis, may present dramatically with blindness. The International Workshop on Ocular Sarcoidosis (2006; revised in 2017) proposed seven clinical signs of ocular inflammation consistent with sarcoidosis including mutton-fat keratic precipitates, trabecular meshwork nodules, snowballs/string of pearls vitreous opacities, multiple chorioretinal peripheral lesions, nodular and/or segmental periphlebitis, optic disc or solitary choroidal nodules, and presence of bilateral disease.[144]

Cardiac Sarcoidosis

Although myocardial sarcoidosis is clinically apparent in less than 10% of cases in the United States at initial diagnosis, autopsy studies suggest the prevalence may be greater than 20% in the United States and greater than 50% in Japan.[145,146] Ventricular and supraventricular arrhythmias, heart block, or sudden death may be the initial manifestation due to involvement of the conduction system.[147] Myocardial inflammation can lead to dilated cardiomyopathy and congestive heart failure, wall motion abnormalities, or aneurysms. Myocardial mass, valvular dysfunction from papillary muscle dysfunction, pericarditis, and myocardial ischemia are rarer manifestations. Cases of isolated cardiac sarcoidosis have been reported, sometimes discovered at time of cardiac transplant surgery or left ventricular assist device implantation.[148] Prior to the availability of advanced cardiac imaging, radiographic scanning using thallium or technetium sestamibi myocardial perfusion scans and gallium uptake scans were used to detect cardiac sarcoidosis. More recently available modalities, such as cardiac FDG PET/CT with paired perfusion SPECT or cardiac MRI with gadolinium contrast, can reveal myocardial inflammation and scarring in a distribution not defined by normal coronary vascular anatomy (Fig. 53-5).[149] The severity of pulmonary involvement does not appear to predict the presence or severity of cardiac sarcoidosis.

Neurosarcoidosis

Neurologic manifestations of sarcoidosis are varied and are estimated to occur in 5% to 10% of patients with sarcoidosis.[150] Cranial neuropathies, with unilateral or bilateral seventh nerve (Bell) palsy being the most common, often resolve spontaneously or with corticosteroids but may recur years later. Optic neuropathy may result in sudden blindness (Fig. 53-6). Impingement of the recurrent laryngeal nerve may cause vocal cord dysfunction. The more typical presentations of sarcoidosis in the brain include a basilar meningitis or aseptic encephalitis, sometimes associated with hypothalamic pituitary dysfunction leading to diabetes insipidus, hypogonadism, or hyperprolactinemia. Meningeal granulomatous masses may mimic meningioma. Sarcoidosis-associated myelopathy (i.e., spinal cord involvement) presents a diagnostic challenge and can present with features that overlap with other inflammatory conditions (e.g. multiple sclerosis) or as a mass-like lesion resulting in paraparesis, hemiparesis, and back and leg pains mimicking radiculopathy.[151] Peripheral neuropathies account for about 20% of cases of neurosarcoidosis, typically presenting as mononeuritis multiplex or a predominant sensory deficit. The presence of a small fiber neuropathy has been demonstrated in a subset of patients with sarcoidosis and can contribute to chronic pain, excessive fatigue, and autonomic dysfunction.[152]

Hepatic Sarcoidosis

Liver biopsies show granulomatous inflammation in over 50% of patients, but clinical manifestations are much less frequent.[153] Active hepatic inflammation may be associated with fever, tender hepatomegaly, or pruritus that may mimic primary biliary cirrhosis except that autoimmune serologies are negative. Characteristically, the serum alkaline phosphatase and γ-glutamyltransferase are elevated proportionately higher than the transaminases or bilirubin, although the latter may be observed with advancing liver dysfunction. Many patients may have asymptomatic involvement of the liver; however, a minority progress to cirrhosis if not treated.

Gastrointestinal Sarcoidosis

Sarcoidosis involvement of the gastrointestinal tract is rare, and symptoms localize to the site(s) of involvement.[154] Occasionally, direct esophageal involvement may cause dysphagia, but more commonly this symptom may be caused by extensive mediastinal lymphadenopathy that impinges esophageal motility. Involvement of the pancreas and peritoneum is rare and challenging to confirm.[155] Gastric sarcoidosis may manifest as dyspepsia, abdominal pain, or gastric nodule. Although autopsy studies show scattered granulomas in the gut, clinically symptomatic intestinal sarcoidosis is rare.

Abdominal Sarcoidosis

A variant of sarcoidosis, often called abdominal sarcoidosis, manifests with liver, spleen, and often bone marrow involvement with hypercalcemia or abdominal lymphadenopathy. Constitutional symptoms are frequent with fevers and fatigue. This “triad” pattern may be seen with or without pulmonary involvement; in the latter instance, intra-abdominal malignancy or infection (e.g., tuberculosis) must be excluded.

Hematologic Sarcoidosis

Persistent, bulky, painful, or disfiguring adenopathy is seen in $<10\%$ of patients, most commonly involving the cervical, supraclavicular, axillary, or epitrochlear lymph nodes. Splenomegaly occurs in $<10\%$ of patients and may be massive and associated with hypersplenism. Because many of the clinical features of sarcoidosis and lymphoma are similar, clinicians should employ heightened awareness to exclude malignancy in patients with a known diagnosis of sarcoidosis who experience new onset of adenopathy and splenomegaly.[156]

Peripheral blood lymphopenia is common in sarcoidosis.[157] Granulomas in the bone marrow are found in about 20% of patients who come to autopsy but usually do not cause symptoms. A known feature of sarcoidosis is the impaired cutaneous response to common antigens that elicit delayed-type hypersensitivity reactions, seen in $>30\%$ of patients. The mechanism is unknown but may be related to alterations in regulatory T-cell function.

Joint and Musculoskeletal Sarcoidosis

Arthralgia is a frequent complaint in sarcoidosis. A short-lived polyarthritis is typical of acute sarcoidosis, usually associated with

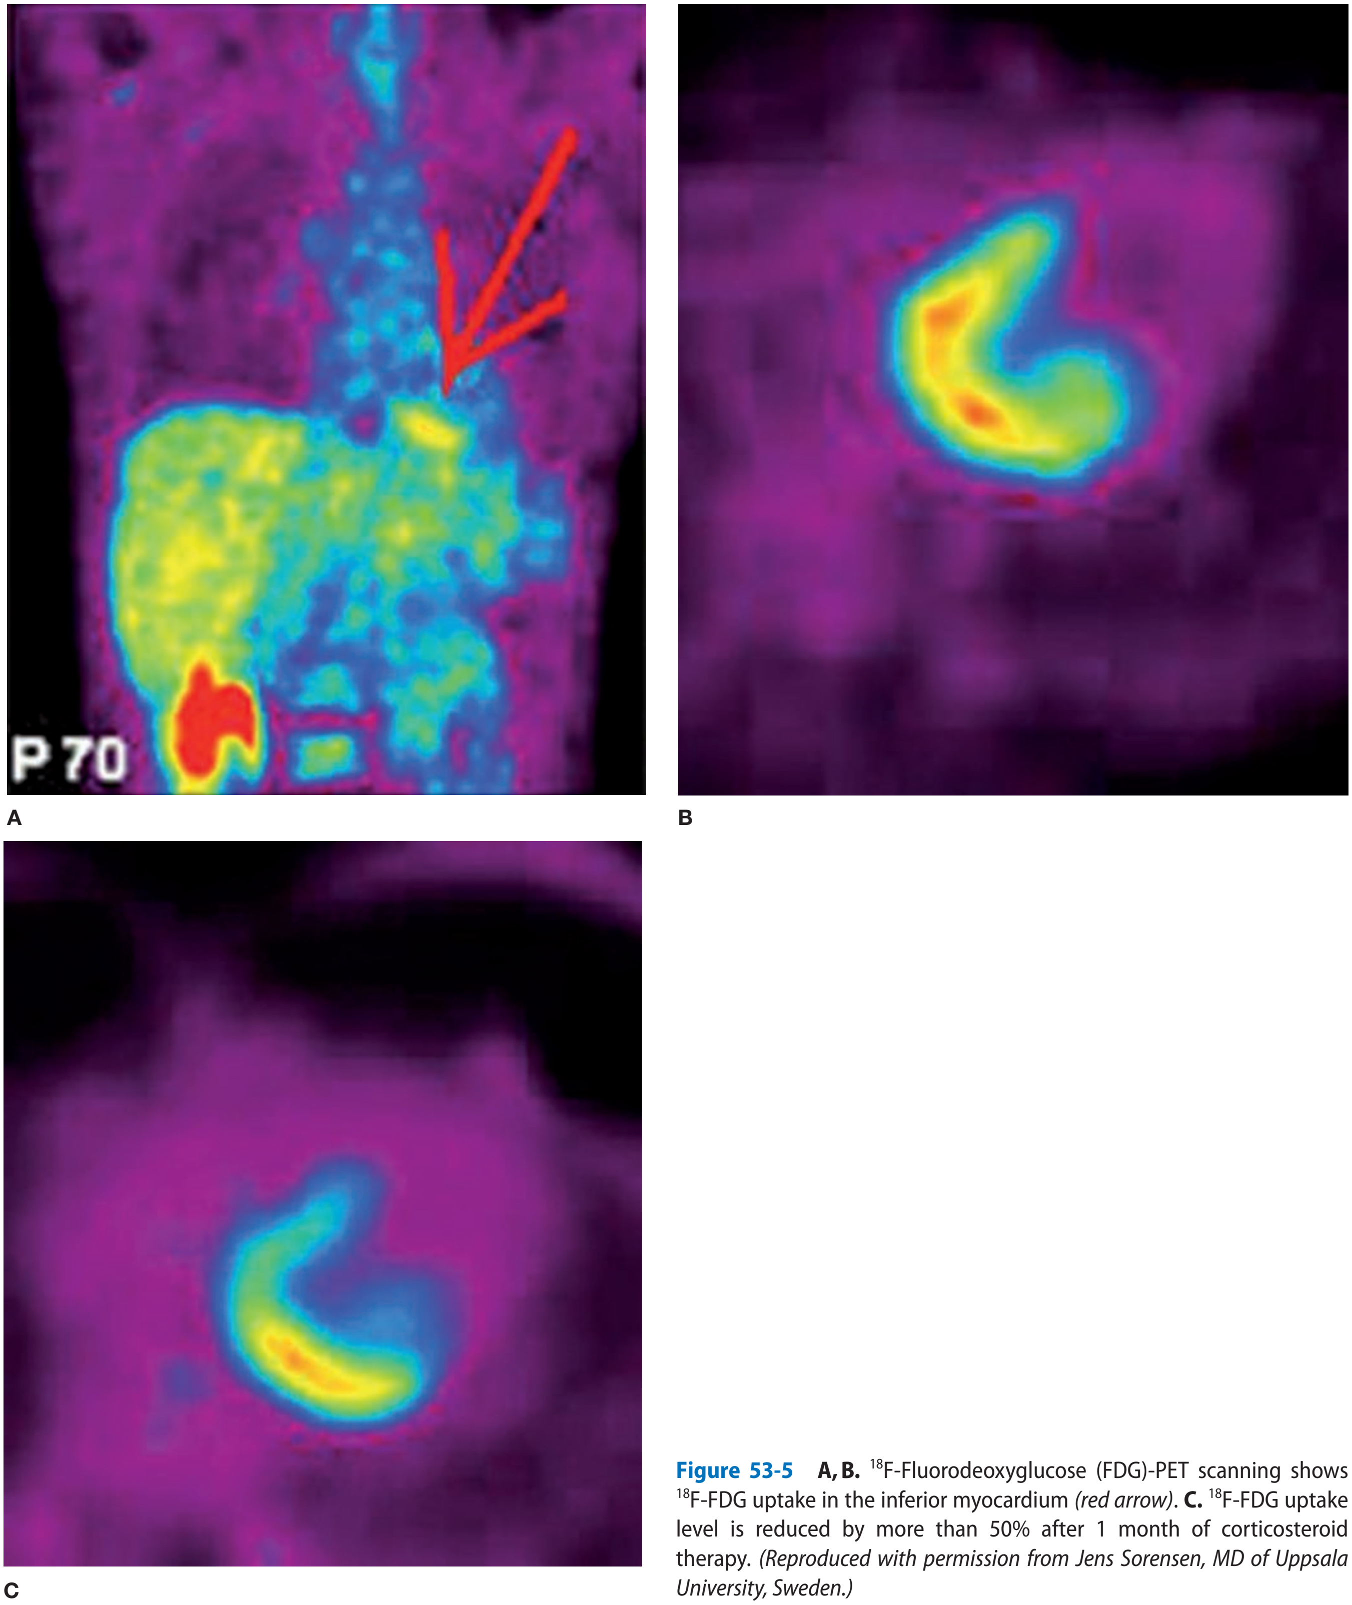

Figure 53-5 **A, B.** ^{18}F-Fluorodeoxyglucose (FDG)-PET scanning shows ^{18}F-FDG uptake in the inferior myocardium *(red arrow)*. **C.** ^{18}F-FDG uptake level is reduced by more than 50% after 1 month of corticosteroid therapy. *(Reproduced with permission from Jens Sorensen, MD of Uppsala University, Sweden.)*

erythema nodosum. Chronic joint disease is found in less than 5% of patients.[158] Joint cartilaginous erosion is rare, but "punched out" bony lesions with cystic changes and loss of bony trabeculae may be seen in subchondral locations. Sarcoidosis is a rare cause of dactylitis, often associated with concomitant cutaneous sarcoidosis. Cystic lesions of the long bones, pelvis, sternum, skull, and vertebrae are uncommon. Sarcoidosis can present as multiple bony lesions on FDG-PET and MRI scans, sometimes as incidental findings without accompanying abnormalities by x-ray or CT imaging suggesting nondestructive infiltration of the bone marrow.[159] Symptomatic myopathy with marked elevation of serum creatinine phosphokinase, aldolase, aspartate aminotransferase, weakness, and tenderness is uncommon. Typically, the myositis from sarcoidosis is responsive to systemic immunosuppression, and recalcitrant cases prompt consideration of alternative diagnosis such as inclusion body myositis.[160]

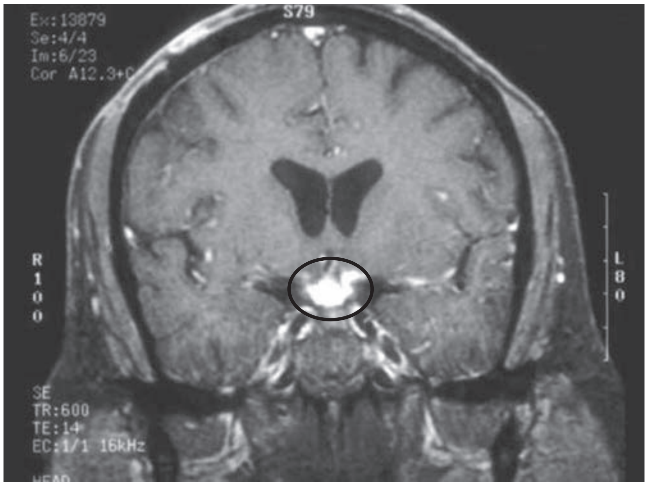

Figure 53-6 Sarcoidosis involving the optic chiasm *(circle)* resulting in blindness.

Exocrine Gland Sarcoidosis

Granulomatous inflammation of salivary, parotid, and lacrimal glands results in enlarged, tender glands and/or sicca syndrome with dry mouth and dry eyes in less than 5% of patients with sarcoidosis. The association of fever, parotid enlargement, facial palsy, and uveitis is known as uveoparotid fever, or Heerfordt syndrome, and is usually accompanied by bilateral hilar adenopathy.

Endocrine Sarcoidosis

Abnormal calcium metabolism is found in sarcoidosis; hypercalciuria is more frequent than hypercalcemia. These abnormalities are due primarily to increased conversion of 25(OH) vitamin D metabolites to active 1,25$(OH)_2$ vitamin D by tissue macrophages and epithelioid cells at sites of granulomatous inflammation.[161] Hypothalamic/pituitary insufficiency may be a manifestation of neurosarcoidosis.

Renal Sarcoidosis

Renal sarcoidosis is considered to be a rare manifestation, but its true frequency is likely underestimated due to a lack of studies judiciously evaluating early signs of renal dysfunction, such as microhematuria and leukocyturia.[162] Kidney stones are the most frequent manifestation of renal sarcoidosis, usually related to abnormal calcium metabolism. Renal failure due to nephrocalcinosis may result from chronic, often asymptomatic hypercalcemia or hypercalciuria. Granulomatous interstitial nephritis is the most typical histologic finding.

Genitourinary Sarcoidosis

Sarcoidosis of the reproductive system has been estimated to occur in less than 1% of clinically diagnosed cases and in 5% of autopsy cases. Genitourinary manifestations of sarcoidosis in men include testicular masses and acute epididymitis-orchiditis. In women, sarcoidosis may manifest with uterine or ovarian involvement that may cause dysmenorrhea or mimic malignancy or fibroids.

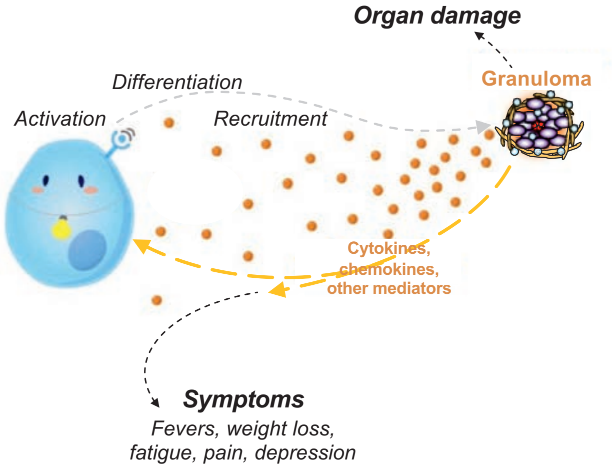

Figure 53-7 Cytokines and other circulating mediators contribute to organ damage by activating cells and directing granuloma formation. Importantly, circulating mediators contribute to patient symptoms through mechanisms other than through direct organ damage, resulting in negative effects on mobility and wellness, adherence, and quality of life.

Psychosocial and Humoral Manifestations

The biological processes involved in sarcoidosis are caused by cytokines and other circulating mediators produced during inflammation. These chemical signals contribute to activation of the immune system, resulting in the initiation and maintenance of granulomatous inflammation that directly causes damage to tissues and organs (Fig. 53-7). However, these chemical signals also contribute to patient symptoms through mechanisms other than direct damage to tissues and organs, and the term *parasarcoidosis syndromes* has been coined to raise awareness of the prevalence of these problems reported by patients. For example, active sarcoidosis can increase the conversion of inactive vitamin D-25OH (sourced from diet and sunlight exposure) into its active form, vitamin D-1,25OH, resulting in hypercalcemia and its secondary effects (osmotic diuresis, fatigue, constipation, altered mental status).[163] Tumor necrosis factor contributes to constitutional symptoms including fatigue and pain, frequently reported among sarcoidosis patients.[164] Depression is also frequently reported among patients with sarcoidosis and can represent a side effect of glucocorticoid treatment but also is hypothesized to be an effect of proinflammatory cytokines.[165–167]

A Dutch study found the prevalence of depression was 4% in asymptomatic patients and 30% in symptomatic patients with sarcoidosis, while the prevalence of depression was found to be 60% in a U.S. study of both white and Black patients with sarcoidosis.[168,169] In this latter study, depression was associated with the female sex, lower socioeconomic status, poor access to care, and increased disease severity, but not race. Using the Hospital Anxiety and Depression Scale (HADS), a German study found that objective scores for anxiety and depression were significantly higher among sarcoidosis patients compared with a control population matched by age and gender, and that dyspnea was an important symptom predicting the presence of anxiety and depression.[170] A recent study found that self-reported depression in sarcoidosis patients was associated with higher health care utilization (emergency department visits) and worse clinical outcomes (lower diffusion capacity) compared to patients without psychological symptoms,[171] supporting the impression that mental illness begets medical noncompliance.[172]

The prevalence of pain in sarcoidosis is unclear, but clinical experience suggests it is common with frequent reports of arthralgias, myalgias, headache, and chest pain, and a subset of patients meets diagnostic criteria for fibromyalgia. However, the cause of pain is often multifactorial with causes including direct granulomatous inflammation of bones, joints, muscles, or peripheral nerves. Additionally, sarcoidosis has been recognized as an inflammatory cause of small fiber neuropathy (SFN).[152,173] Although SFN can result as a complication from chronic inflammation, treatment with immunosuppression medications is often ineffective once SFN is manifest. In addition to its association with pain, SFN may cause autonomic dysfunction with gastrointestinal dysmotility, incontinence or retention, sicca syndrome, flushing, sweats, orthostatic hypotension, and sexual dysfunction.[174]

■ Associated Conditions

Important selected conditions associated with sarcoidosis are discussed briefly below.

Sarcoidosis and Pregnancy

There is usually little long-term effect on the course of sarcoidosis from pregnancy. In contrast to diseases such as asthma and systemic lupus that may progress during pregnancy, spontaneous improvement in chronic sarcoidosis has been reported in some patients during pregnancy, although exacerbations often follow several months after delivery. The reasons for the temporary clinical improvement are not known but might be related to suppressed Th1 immunity during pregnancy associated with enhanced Treg function. A population-based retrospective cohort study found that sarcoidosis was associated with higher rates of obstetrical complications but not maternal death.[175]

Altered Th1 Immunity

Sarcoidosis is associated with several clinically disparate situations associated with altered, enhanced Th1 immunity. The clearest example involves the administration of Th1-promoting therapeutics such as IFN-α, IFN-γ, IL-2, and IFN-β that may be associated with initiation or recrudescence of sarcoidosis.

Common Variable Immunodeficiency Granulomatous inflammation has been identified in several immunodeficiency states, particularly in patients with hypogammaglobulinemia secondary to common variable immunodeficiency (CVID). Within subsets of patients with CVID, case series reports suggest that a diagnosis of concurrent sarcoidosis can be inferred by a compatible history of systemic illness and confirmed by biopsy.[176] In other CVID patients who present with dominant pulmonary manifestations, CVID-associated granulomatous-lymphocytic interstitial lung disease may be present and is often resistant to treatment.[177] Since CVID occurs at any age, a high index of suspicion must be maintained, particularly in sarcoidosis patients who have recurrent infections or in any child with sarcoidosis given the low frequency of sarcoidosis in this age group.

Human Immunodeficiency Virus Sarcoidosis may develop in HIV-infected patients with immune reconstitution following initiation of highly active antiretroviral therapy, perhaps from reconstituted Th1 immunity.[57] Granulomatous inflammation of the lungs or skin is most often reported.

Autoimmune Disorders Sarcoidosis is associated with a variety of disorders of the immune system, such as Crohn's disease, ulcerative colitis, primary biliary cirrhosis, scleroderma, Sjögren syndrome, autoimmune hemolytic anemia, and autoimmune endocrinopathies.[178] Given the rarity of some of these disorders, it is reasonable to postulate that these associations are the result of a common immune disturbance, with altered Th1/Th17 immunity that may predispose to both disorders.

Recently, a syndrome of immune-mediated disorders in patients with elevated serum IgG4 levels has been described, commonly presenting as adenopathy, constitutional symptoms, and mass-like tumors.[179] Granulomatous inflammation is observed in a subset of patients mimicking sarcoidosis, and an evaluation for IgG4-related disease should be considered in patients who have clinical features atypical for sarcoidosis, such as recalcitrant eosinophilia, pancreatitis, or multiple endocrinopathies.

Cancer Noncaseating granulomas may be seen within or near 3% to 10% of tumors and in approximately 4% of regional draining lymph nodes.[180] Less commonly, multisystem granulomas consistent with systemic sarcoidosis develop in patients with a recent or past diagnosis of cancer or following chemotherapy treatment. Often the diagnosis is established by biopsy of enlarged lymph nodes or lung where the presurgical diagnosis is recurrent malignancy.[181] There is usually little functional lung impairment from pulmonary sarcoidosis in these instances, and treatment is often unnecessary with eventual remission. A possible link involves dysregulated Th1/Th2 immunity, a premise supported by several cases of sarcoidosis developing in patients with changes that result in deletion of several Th2 genes (IL4, IL13, CSF2).[182] Along this vein, induction of a sarcoidosis-like granulomatous inflammation may complicate the administration of immunotherapy for cancer.[183]

Pediatric Sarcoidosis

Sarcoidosis is significantly less prevalent among children compared with adults, and sarcoidosis is rare in the preteen ages.[184] Early-onset disease in children under 5 years of age typically involves skin, eye, and joint involvement that has considerable clinical overlap with juvenile rheumatoid arthritis or Blau syndrome, an autosomal dominant granulomatous disease caused by a NOD2 mutation.[185] This form of sarcoidosis carries a much worse prognosis than disease presenting in older children. In the teenage years, clinical manifestations and prognosis in children is similar to that of adults. Pediatric sarcoidosis may also be associated with CVID.

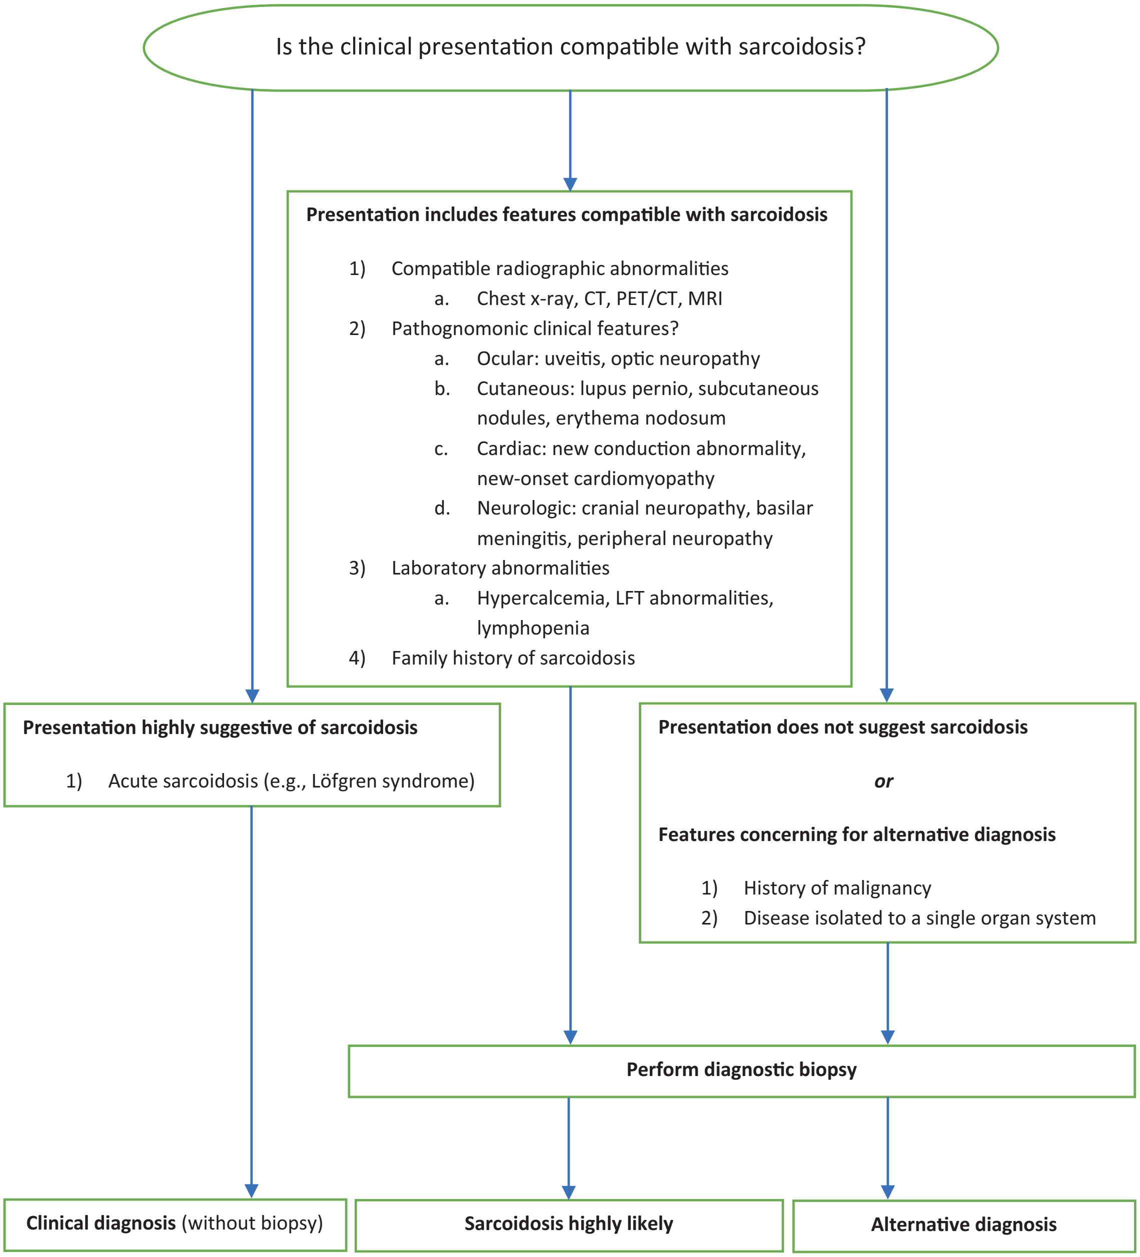
Sarcoidosis in the Elderly

Recurrent sarcoidosis after many years, even decades of apparent remission, is also seen, often manifesting with recrudescence of original manifestations, or with new-onset neurologic or cardiac involvement.

DIAGNOSTIC APPROACH

There is no reliable, noninvasive screening test to help confirm a diagnosis of sarcoidosis. A diagnosis of sarcoidosis is based on compatible clinical and radiologic manifestations together with a tissue biopsy demonstrating noncaseating granulomatous inflammation and exclusion of other granulomatous disorders (Fig. 53-8). Exceptions to this approach include patients who manifest with Löfgren syndrome in areas with a low prevalence of histoplasmosis, which may mimic Löfgren syndrome, in which case most experts believe a biopsy is not necessary.[186] Many experts suggest that patients with asymptomatic bilateral hilar adenopathy with presumptive stage I sarcoidosis do not need biopsy unless atypical features are present, given a low pretest probability for alternative diagnoses and the risks for potential complications of a diagnostic biopsy.[187,188] Clinical involvement of more than one organ system helps exclude local granulomatous reactions to foreign bodies, infection, or malignancy. The decision to obtain a confirmational biopsy in patients with presumed stage I sarcoidosis presenting as asymptomatic bilateral hilar adenopathy relies on an individualized assessment of a patient's cancer and/or occupational risk factors, risks associated with biopsy approach, local prevalence of infectious diseases (e.g., tuberculosis, endemic fungus), and the availability and feasibility of close medical follow-up.[2]

In general, the easiest accessible biopsy site can be approached to confirm a diagnosis of sarcoidosis. Biopsy of a skin or conjunctival nodule, enlarged superficial lymph node, or lacrimal gland may help to establish a diagnosis. Noncaseating granulomas on a liver or bone marrow biopsy are nonspecific and support a diagnosis only when competing diagnoses such as infection, drug reaction, or malignancy are excluded.



Is the clinical presentation compatible with sarcoidosis?
Presentation includes features compatible with sarcoidosis
1) Compatible radiographic abnormalities
a. Chest x-ray, CT, PET/CT, MRI
2) Pathognomonic clinical features?
a. Ocular: uveitis, optic neuropathy
b. Cutaneous: lupus pernio, subcutaneous nodules, erythema nodosum
c. Cardiac: new conduction abnormality, new-onset cardiomyopathy

Sarcoidosis highly likely
Alternative diagnosis

Figure 53-8 Diagnostic approach for evaluation of possible new case of sarcoidosis.

When a more easily accessible site is not available, biopsy by fiberoptic bronchoscopy remains the most common approach because of its high yield and relative safety. The diagnostic yield of transbronchial biopsy (TBB) is estimated to be >40% even in patients with a stage I chest radiograph and approaches 80% in the presence of lung infiltrates.[189] Transbronchial lung biopsy in advanced fibrocystic sarcoidosis has a low yield, owing to extensive fibrotic changes. Sampling by endobronchial mucosal biopsy (EMB) and transbronchial needle aspiration (TBNA) of thoracic lymph nodes provides additional sensitivity when combined with TBB.[190] The sensitivity of endoscopic bronchial ultrasound (EBUS)-guided TBNA has been found to be superior to standard TBNA in diagnosis of sarcoidosis.[191] Transbronchial lung cryobiopsy may improve diagnostic yield in challenging diagnostic situations but may be associated with higher rates of complications compared with other bronchoscopic techniques.[192] In cases of suspected malignancy, mediastinoscopy or surgical lung biopsy may be needed for histologic diagnosis.

Bronchoalveolar lavage obtained as part of a diagnostic bronchoscopy remains an important method for excluding infectious causes of granulomatous inflammation. Some studies suggest that a BAL T cell CD4:CD8 ratio >3.5 supports a diagnosis of sarcoidosis but may not differentiate some infectious or noninfectious inflammatory lung diseases.[193]

A diagnosis of cardiac sarcoidosis is usually established by a noncardiac biopsy confirming systemic sarcoidosis along with consistent myocardial imaging studies or rhythm disturbances (Fig. 53-5). Endomyocardial biopsy is positive in <20% of cardiac sarcoidosis owing to sampling inefficiencies and the infrequency of right ventricular involvement; thus a negative biopsy never excludes cardiac sarcoidosis.[194]

A diagnosis of neurosarcoidosis is usually confirmed by biopsy of a non-CNS site.[195] Rarely, brain biopsy is needed to exclude infectious or malignant disease.

For organs that are rarely involved in sarcoidosis, directed biopsy of the involved tissue is often recommended to exclude alternative causes, even when there is documentation of a prior biopsy that confirmed an original diagnosis of sarcoidosis.[196] For organs that are difficult to biopsy, ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) scanning, or contrast-enhanced MRI scanning have replaced ^{67}gallium scans in helping define sites of clinically occult inflammation that could provide an alternative biopsy approach.[197]

Laboratory tests are generally not helpful in confirming a diagnosis of sarcoidosis but may assist in establishing an alternative diagnosis, such as autoimmune disease. A diagnostic biomarker has not been identified for sarcoidosis. Serum angiotensin-converting enzyme (sACE) levels are elevated in 30% to 80% of patients with clinically active disease from activated epithelioid cells and macrophages at sites of inflammation, but can be also seen in infectious granulomatous diseases, pneumoconiosis, cirrhosis, diabetes, thyroid disease, and autosomal dominant familial clustering; thus sACE lacks specificity as a diagnostic tool.[198]

CLINICAL ASSESSMENT

Once a diagnosis is established or suspected, an initial evaluation should consist of tests to evaluate the presence and extent of pulmonary involvement and assess the presence and severity of extrathoracic disease (Table 53-5).

Specialized testing is indicated when symptoms or signs suggest extrapulmonary sarcoidosis. Guidelines for when and how to screen for potential cardiac involvement remain uncertain.[2,147,199,200] Due to its low cost and wide availability, all patients should have a yearly ECG.[2] Screening for cardiac sarcoidosis is recommended whenever symptoms such palpitations, near-syncope/syncope, orthopnea, or leg edema are present.[201] A second-level screening may include a Holter monitor, signal-averaged ECG, and echocardiogram to detect conduction abnormalities impaired, heart rate variability, or myocardial dysfunction. Advanced cardiac imaging with cardiac MRI with gadolinium enhancement or cardiac FDG-PET scanning is recommended for those patients with continued uncertainty of possible cardiac sarcoidosis. Unexplained dyspnea or chest pain may also be suggestive for sarcoidosis but may also prompt investigations for other etiologies such as pulmonary hypertension or esophageal dysmotility, respectively.[152] Thallium or technetium sestamibi myocardial scanning, in conjunction with cardiac FDG-PET or MRI, is useful to exclude coronary artery disease and may detect patchy fixed or reverse ischemia–perfusion defects consistent with myocardial inflammation or fibrosis.[202] Electrophysiologic testing may be indicated to exclude arrhythmias not detected by routine studies and assess indications for cardiac pacemaker or implantable defibrillator to reduce the risk of sudden death.[203] The presence of myocardial scar is associated with increased risk for arrhythmogenic events and all-cause mortality.[204]

TABLE 53-5 Suggested Tests for Initial Sarcoidosis Clinical Evaluation

All Patients	Organ-Specific Testing for Suspected Involvement
Chest radiograph or chest CT	Cardiac: echocardiogram, Holter monitoring, cardiac MRI, cardiac PET
Pulmonary function tests: spirometry, diffusing capacity, lung volumes	Neurologic: brain or spine MRI with gadolinium enhancement, cerebrospinal fluid examination, nerve conduction studies, small fiber nerve analysis
Ophthalmologic examination	Upper respiratory tract: flow-volume loop, ENT evaluation
Complete metabolic panel	Endocrine: pituitary function tests; thyroid function tests
Complete blood count with differential count	Kidney stones: vitamin D-1,25OH, parathyroid hormone level, 24-h urine calcium
Electrocardiogram	Renal: Urinalysis, renal biopsy
IFN-γ release assay	Cutaneous: skin biopsy

Evaluation for possible CNS and spinal sarcoidosis should include MRI with gadolinium enhancement, now considered the optimal test to detect characteristic inflammatory lesions.[195] The distribution of inflammatory loci has a propensity for periventricular and leptomeningeal areas, although the images are nonspecific and can be produced by infectious, malignant, or occasionally demyelinating disease.[151] A normal scan does not exclude neurosarcoidosis, particularly for cranial neuropathies or in the presence of corticosteroid therapy. Examination of the cerebrospinal fluid may be useful for demonstrating characteristic lymphocytic pleocytosis and/or elevated protein levels, and to exclude infection and hydrocephalus in select cases. For suspected peripheral neuropathy or myopathy, EMG or nerve conduction studies or, rarely, tissue biopsy may help to establish a link to sarcoidosis. Specialized evaluation including skin biopsy analysis of intraepidermal nerve fiber density and neurophysiologic testing may be indicated to confirm cases of small fiber neuropathy.[152]

CLINICAL COURSE AND PROGNOSIS

A clinical framework can be constructed to assist in decisions regarding monitoring and planning treatment strategies. First, organ involvement usually defines itself early in the disease. For example, only 23% of patients in the ACCESS study were found to have one or more new organ systems involved with sarcoidosis during a 2-year follow-up evaluation; the presence of extrapulmonary involvement at presentation was a risk factor for new organ development.[128] Second, patients who undergo remission usually do so within the first 2 to 3 years. Clinical experience suggests sarcoidosis rarely recurs after a prolonged period of remission, with exceptions most often involving neurologic or ocular manifestations. Third, patients with chronic sarcoidosis generally have progressive, unremitting organ impairment. High rates of relapse (>50%) are observed in patients requiring systemic immunosuppressive medications compared with those who experience spontaneous disease remission (<10%).[205–207] In these patients, the rate of progression varies from individual to individual, as does their response to treatment. A waxing–waning clinical course is uncommon except for a subset of patients with neurologic or ocular manifestations or occasionally recurrent erythema nodosum. Fourth, prognosis in sarcoidosis is strongly influenced by the initial manifestations of disease. Patients with Löfgren syndrome have remission rates of 70% to 80%. An initial stage I chest radiograph is associated with a 60% to 90% remission rate. Patients manifesting with type II chest radiographs have a poorer outcome, with spontaneous remission occurring 40% to 70% of the time. A stage III chest radiograph is associated with remission in only 10% to 20% of patients. Patients with extensive pulmonary fibrosis (stage IV) rarely undergo remission.

Currently, a consensus recommendation is that treatment decisions are best based on repeated clinical examinations and direct measurement of organ function and not on laboratory markers of disease "activity."[1,18,208] SACE levels tend to correlate with the extent of granulomatous inflammation throughout the body, particularly when interpreted in the context of known polymorphisms of ACE alleles, and usually decrease in response to corticosteroids or with disease remission—but the test is highly variable, correlates poorly with functional assessments of disease activity, and has no prognostic value. Similarly, BAL parameters such as the proportion of CD4 lymphocytosis or the CD4:CD8 ratio of BAL T cells have been inconsistent in predicting outcomes. Many inflammatory molecules have been proposed as helpful biomarkers for disease activity including sIL2R, TNF, and neopterin but are not reliable prognostic indicators.[209] PET/CT scans can be considered to detect and monitor evidence of inflammation in select cases (such as cardiac and neurologic involvement), but given the cost and risk associated with radiation exposure, further evaluation is needed to confirm its prognostic value and appropriate role for long term management.[210] More recently, studies suggest transcriptomic signatures may be useful for prognosis, but there are no currently validated markers useful for clinical purposes.[211] Monitoring for at least 3 years following presumed "disease remission" is recommended; longer periods of observation are indicated for patients with serious pulmonary or extrapulmonary manifestations.

TREATMENT

A variety of approaches have been utilized in the treatment of sarcoidosis and are outlined in this section. There are no FDA-approved systemic therapies for sarcoidosis.

Indications for Treatment

There have been attempts to provide evidence-based recommendations for treatment of sarcoidosis, but the lack of placebo-controlled clinical trials in this highly heterogeneous disease have made firm conclusions problematic. Most physicians agree that corticosteroid or other systemic therapy is indicated for the manifestations listed in Table 53-6.

Indications for treatment must account for the overall excellent prognosis for most patients with sarcoidosis, particularly for patients with stage I disease, for whom systemic therapy is usually not required. Symptomatic or local therapy is recommended whenever possible. Löfgren syndrome is usually managed with bed rest and nonsteroidal anti-inflammatory drugs; corticosteroids are recommended when symptoms, particularly arthritis, are disabling and persistent.

Corticosteroid Therapy

Corticosteroids remain the cornerstone of therapy for sarcoidosis. Although controversy exists regarding the overall effectiveness of corticosteroids in altering the long-term course of the disease, there is no disagreement that corticosteroids provide prompt symptomatic relief and reverse organ dysfunction in most patients with the degree of reversibility dependent on the extent of pre-existing fibrosis. Case series and several but not all clinical trials support the view that corticosteroids favorably affect disease outcome in chronic pulmonary sarcoidosis. One large study by the British Thoracic Society found long-term improved lung function in patients with stage II or III pulmonary disease treated with daily corticosteroid therapy compared with a group treated intermittently with corticosteroids based on symptoms.[205]

TABLE 53-6 Indications for Treatment of Sarcoidosis

Threatened organ failure • Severe ocular, cardiac, or neurologic disease
Uveitis unresponsive to topical corticosteroids
Progressive, persistent, or symptomatic pulmonary disease
Disfiguring cutaneous disease, especially lupus pernio on the face
Persistent hypercalcemia, renal or hepatic dysfunction
Symptomatic hepatic or splenic enlargement, hypersplenism (sequestration)
Symptomatic myopathy
Painful lymphadenopathy
Severe fatigue and weight loss

Optimal dosing of corticosteroid therapy has not been established by clinical trials. Most authorities suggest that initial treatment of pulmonary sarcoidosis usually does not require more than 20 to 40 mg per day of prednisone followed by a slow taper to a maintenance dose of 5 to 15 mg per day of prednisone.[212] Every-other-day dosing of prednisone may be effective in some but not all patients. Treatment is usually continued for a minimum of 6 to 24 months, since premature attempts to taper off steroids are likely to result in relapse of disease. Inhaled steroids appear to have limited effectiveness in chronic pulmonary sarcoidosis and are not recommended as sole therapy. Overall, chronic progressive pulmonary disease occurs in more than 20% of patients as oral corticosteroids are tapered or discontinued. Treatment of extrapulmonary sarcoidosis is modeled after the general approach to pulmonary sarcoidosis (Table 53-7), with special considerations for specialized testing and concerns based on specific organ involvement. Extrapulmonary sarcoidosis may require higher doses of corticosteroids, especially for cardiac, neurologic, and severe ophthalmologic cases and warrant collaboration with a specialist.

Alternative Agents

Several classes of drugs have been reported to be beneficial in subgroups of patients with sarcoidosis, but none of these drugs has been proven effective by rigorous clinical trials.

Nonimmunosuppressive Drugs

Case series suggest hydroxychloroquine is effective in many patients with mucocutaneous sarcoidosis, in those with hypercalcemia, and, occasionally, as a steroid-sparing agent in systemic sarcoidosis. Ocular toxicity is rare, and its overall safety profile provides a rationale for an early trial of this drug. Chloroquine may be

TABLE 53-7 Suggested Initial Management for Sarcoidosis

	Initial Prednisone Dose (mg/d)	Testing *Special Management Concerns*
Pulmonary	20–40	Biopsy, PFTs, chest x-ray, chest CT *Airway reactivity, pulmonary hypertension, sleep apnea*
Cutaneous[T]	20	Biopsy *Intralesional corticosteroid injections, hydroxychloroquine*
Sinonasal[T]	20–40	Biopsy, CT scan, laryngoscopy *Nasal irrigation, topical corticosteroids*
Hepatic	20	Biopsy, MRI *Cirrhosis*
Cardiac	40	ECG, echo, Holter, PET/CT, MRI *CHF management, electrophysiology study, cardiac device*
Neurologic[IV]	40–80	MRI with gadolinium, lumbar puncture *Small fiber neuropathy, hydrocephalus, neurorehabilitation*
Ocular[T, IV]	40–80	Urgent ophthalmology evaluation *Dry eye syndrome, occluded tear ducts*

[T] *Topical corticosteroids are often a first-line consideration.*

[IV] *Intravenous pulse-dosed corticosteroid are often considered for severe cases.*

efficacious in treating lupus pernio, SURT, or sinus disease, which is often recalcitrant to other therapies, although ocular toxicity has limited its use.

The tetracyclines minocycline and doxycycline may be effective in a subgroup of patients with mild cutaneous sarcoidosis but rarely as a steroid-sparing drug in systemic disease. These antibiotics have mild anti-inflammatory effects (possibly through effects on the host microbiome), which probably account for their mechanism of action given that other antibiotics with similar antimicrobial activity have not been found effective in sarcoidosis.

Case series supported the use of adrenocorticotropic hormone (ACTH) for treating sarcoidosis prior to the wide availability of oral corticosteroid medications.[213] In addition to supporting the natural production of cortisol, ACTH can interact through melanocortin receptors, which demonstrate possible anti-inflammatory effects in experimental models.[214] Therefore, ACTH has reemerged as a treatment consideration for sarcoidosis, but whether the primary systemic effect of ACTH administration is through augmenting cortisol production is unknown. Prospective studies are needed to confirm the role of ACTH for treating sarcoidosis, particularly whether ACTH (typically administered as repeated injections) has any safety (and cost) benefits compared to oral corticosteroids.

Pentoxifylline is a phosphodiesterase inhibitor with anti-inflammatory effects that was found to be effective in early pulmonary sarcoidosis in one study.[215] Other experiences have not been as favorable with responses in less than 10% of patients, generally those with mild pulmonary or systemic sarcoidosis.

Melatonin was found to be beneficial in a small case series of patients with generally mild disease, but wider experience has not confirmed its efficacy.

Thalidomide was found in one study to be beneficial in more than 80% of patients with severe skin sarcoidosis (lupus pernio unresponsive to other therapies) but was not effective in pulmonary sarcoidosis.[216] Given the drug's well-known teratogenicity and potential to cause peripheral neuropathy and sedation, the drug is recommended only in patients refractory to other treatments.

Immunosuppressive Drugs

Clinical experience in sarcoidosis suggests that all noncorticosteroid immunosuppressive therapies share the following characteristics: beneficial responses are seen in no more than 50% to 70% of patients; responses may take 3 to 6 months or longer; low-dose corticosteroid therapy is often needed for synergistic effect to obtain adequate suppression of granulomatous inflammation. Dosing and monitoring for these therapies should follow the recommendations of the American College of Rheumatology.[217]

Methotrexate is often the first immunosuppressive therapy used as an alternative therapy for refractory pulmonary or systemic sarcoidosis when corticosteroid and antimalarial therapies are ineffective or poorly tolerated. Hepatic, pulmonary, and renal toxicities limit the use of the drug. Azathioprine has shown benefit in small clinical trials and is used by some authorities as an initial potent steroid-sparing therapy. Clear advantages of methotrexate or azathioprine over low-dose corticosteroids in the routine management of sarcoidosis have not been established. Other immunosuppressive agents, such as mycophenolate mofetil, leflunomide, or cyclophosphamide, have been found beneficial in a small series of patients with manifestations of sarcoidosis refractory to corticosteroids.

Small studies have shown that cyclosporine and FK506, drugs known to inhibit T-cell activation, are not effective in pulmonary or ocular sarcoidosis or in suppressing recurrent sarcoidosis in transplants. Given their toxicities, consensus is to avoid these medications until new studies demonstrate potential benefits.

Anti-TNF Therapies and Other Biologic Agents

The scientific basis for the use of TNF inhibitors in sarcoidosis is firmly established based on the role of TNF in experimental models of granuloma formation. One multicenter study found infliximab to be effective in one of several primary endpoints (improved FVC after 24 weeks of therapy), although the effect was modest.[218] Etanercept was not shown to be effective in a smaller clinical trial of pulmonary sarcoidosis.[219] Successful treatment with rituximab has been reported in individual cases, particularly for the treatment of ocular or CNS manifestations, but the results from case series has been inconsistent.[220] Other biologic agents targeting other mechanisms involved in sarcoidosis (anti-IL12, anti-IL6, anti-CTLA4) also may be useful for treating patients who have not benefited from other treatments, but given the risk profiles of these agents, additional clinical trials are warranted to evaluate their appropriate therapeutic role.[221–223]

■ Special Circumstances

Several special considerations in the management of systemic sarcoidosis deserve particular mention.

Fibrocystic Sarcoidosis

Advanced pulmonary sarcoidosis may be complicated by mycetomas, usually from *Aspergillus fumigatus*, that colonize pre-existing cystic spaces. The fungi rarely cause invasive disease. Spontaneous resolution may be seen. The benefit of antifungal agents has not been established, but they may be used for serious hemoptysis. Massive hemoptysis associated with mycetomas or bronchiectasis may be life-threatening, requiring therapeutic embolization of the appropriate bronchial or collateral artery for control. Surgery is usually not feasible because of the severe restrictive lung disease.

Pulmonary Hypertension

Moderate or severe pulmonary hypertension is an independent predictor of reduced survival in patients with advanced lung disease awaiting lung transplantation.[133] Outcomes are associated with the severity of pulmonary hypertension, warranting the evaluation of strategies for early screening.[137] Management options include immunosuppression to control active sarcoidosis inflammation and agents targeting pulmonary hypertension, but longitudinal studies are needed to determine the roles of these therapies.[136]

Cardiac Sarcoidosis

Several large case series find prognosis in cardiac sarcoidosis, and response to treatment is related to the degree of cardiac dysfunction. Treatment of cardiac sarcoidosis consists of antiarrhythmic therapy, diuretics, and afterload-reducing agents for specific cardiac abnormalities. Although randomized trials are lacking, studies from Asia, Europe, and the United States consistently report that corticosteroids in moderate doses are associated with improved cardiac function and outcomes.[224,225] Maintenance doses of prednisone often range between 10 to 25 mg a day, although higher doses may be needed for intractable arrhythmias. Immunosuppressive drugs, including anti-TNF agents, are frequently used as steroid-sparing agents since treatment often must be maintained for years.[226] Automatic implantable cardioverter-defibrillators (ICDs) may prevent sudden death in patients with serious arrhythmias.[147,203,204]

Neurosarcoidosis and Ocular Sarcoidosis

High doses of oral corticosteroids or high-dose pulse intravenous therapy are often indicated for serious ocular or CNS disease, such as optic neuritis or encephalitis followed by maintenance corticosteroid or immunosuppressive therapy. Anterior uveitis can usually be treated with topical ophthalmologic steroid drops; intraocular corticosteroid injections can be used in more aggressive cases in patients who do not have extraocular sarcoidosis. Systemic immunosuppression may be necessary in cases of severe disease, and the use of steroid-sparing agents including TNF inhibitors should be considered to limit the risk of corticosteroid-related complications. Neuro-ophthalmologic sarcoidosis is often associated with chronic disease activity, and relapses frequently occur in some patients on de-escalation or withdrawal of therapy.[227] Small fiber neuropathy typically does not reliably respond to corticosteroid therapy, prompting trials of neuropathic drugs, TNF inhibitors, or other novel agents.[152,228]

Pregnancy

Corticosteroids are the only drugs recommended for use during pregnancy because of the potential for other steroid-sparing drugs to cause fetal toxicity or teratogenicity. Sometimes, spontaneous abatement of chronic sarcoidosis occurs in pregnant patients, allowing a temporary reduction in steroid dosage. After pregnancy, however, an exacerbation often occurs, requiring a return to the original maintenance dose.

■ Quality of Life

There is increasing recognition of the need to treat depression and pain to improve quality of life in patients with these manifestations.[229] The utility of nonpharmacologic treatments, such as exercise training or pulmonary rehabilitation, merits investigation because of the impact of these problems in sarcoidosis patients.[230]

■ Lung and Heart Transplantation

Although advanced lung disease from sarcoidosis can be successfully controlled with long-term use of immunosuppression medications, sarcoidosis patients referred for lung transplantation experience high rates of mortality.[231] Successful lung, heart–lung, and heart transplantations have been performed in patients with advanced pulmonary sarcoidosis or cardiomyopathy. Although noncaseating granulomas have been found in some transplanted lungs or hearts, these findings do not appear to significantly affect outcome.[232,233] Outcomes for lung transplant in sarcoidosis are similar to other interstitial lung diseases.

CHAPTER 54

Idiopathic Pulmonary Fibrosis

Tanzira Zaman
Giuliana Cerro Chiang
Paul W. Noble

INTRODUCTION

Interstitial lung disease (ILD) is a heterogenous group of inflammatory and scarring conditions of the lung. Idiopathic pulmonary fibrosis (IPF) is a distinct form of ILD and represents a specific clinical entity defined by a constellation of clinical, radiographic, and pathophysiologic features. Other forms of cryptogenic ILD that do not fit into the diagnostic criteria for IPF are referred to as "unclassifiable" ILD, although some may, in fact, show a clinical trajectory that matches IPF.

IPF is the most common ILD with heterogenous and complex pathophysiology without a clear causative etiology (except in the case of familial disease). A diagnosis of IPF is made most confidently when a high-resolution computed tomography (HRCT) or histopathologic pattern of usual interstitial pneumonia (UIP) is observed in the absence of an identifiable trigger. Such etiologies include connective tissue disease, environmental exposures leading to hypersensitivity reactions, and drug-induced fibrosis. In other words, UIP is not synonymous with IPF; other etiologies of UIP must be excluded for the diagnosis of IPF.

Considered a disease of aging, IPF usually presents in the seventh decade of life. The symptoms and physical examination findings of IPF are nonspecific and can thus lead to substantial delays in diagnosis, especially as there are far more common pulmonary and cardiac abnormalities that present similarly. As will be discussed further, the scope of current therapies for IPF render them of greatest benefit earlier in the course of disease, so timely diagnosis is of importance from a therapeutic standpoint. Diagnostic delays also contribute to patient distress, and as depression and anxiety are common comorbidities in IPF, earlier establishment of a definitive diagnosis can contribute to a patient's peace of mind and ability to cope with chronic illness.

The clinical course of IPF is one of certain, yet unpredictable, progression. Long-term observational studies of patients with IPF reveal that while decline in lung function is inevitable, there is a paucity of reliable predictors to identify which patients are at risk for progression. Similarly, there are no reliable means to identify which patients are at risk for acute exacerbations of disease or when such exacerbations are likely to occur, which provides a challenge in counseling patients on prognosis and determining the ideal timing for what remains the only definitive "cure" for IPF: lung transplantation.

Biomedical research in recent years has yielded new insights into the genetic predisposition to IPF, the pathogenic pathways that are potentially targetable with experimental therapies, and molecular markers to discriminate IPF from non-IPF ILD. However, there remains an unmet need to develop medications that not only slow disease progression, but halt progression of disease entirely.

HISTORIC PERSPECTIVE

A brief review of the evolution in our understanding of IPF illustrates the contributions made by earlier investigators but also reveals the reasons for the confusion that many clinicians have regarding IPF. One of the challenges in defining IPF has been the variety of antiquated terms formerly used to describe pulmonary fibrosis. While there are many causes of ILD in general, and pulmonary fibrosis in particular, it is important to note that IPF is a unique disease rather than a catch-all term for any and all idiopathic interstitial pneumonias (IIP). A review of the history of IPF will both clarify the present terminology and distinguish contemporary nomenclature from the outmoded terms encountered in earlier literature.

Fibrosis of the lung was long recognized in association with infection or dust inhalation. In the 19th century, pulmonary fibrosis was known as "cirrhosis of the lung"; little attention was paid to this form of respiratory illness.[1] Interest in pulmonary fibrosis was ignited in 1944 when Louis Hamman and Arnold Rich published a seminal paper describing "acute diffuse interstitial fibrosis of the lungs."[2] Hamman and Rich reported a series of unusual cases that shared a unique clinical presentation featuring idiopathic subacute respiratory failure followed by death. Their report was complete with pathologic findings from autopsy. They described thickening of the alveolar interstitium and areas of dense fibrotic scar tissue within the lung, the first pathologic depiction of pulmonary fibrosis. In retrospect, the cases of Hamman and Rich best fit a diagnosis of the fibrosing interstitial pneumonia now known as acute interstitial pneumonitis (AIP).[3] However, in the 1940s, the "Hamman–Rich syndrome" became synonymous with IPF, and so it remained for the next three decades.

Over the years, clinical reports of pulmonary fibrosis suggested a number of alternate presentations that were referred to as "variants" of the Hamman–Rich syndrome.[4] This included cases that exhibited a rather protracted duration of illness compared with the "classic" Hamman and Rich cases. It was also noted that pulmonary fibrosis occurred in patients who suffered from the "rheumatoid group of collagen diseases." An assortment of abnormal patterns was noted under the microscope. Eventually, the breadth of the Hamman–Rich syndrome encompassed a heterogeneous mixture of clinical manifestations and a variety of histologic forms of pulmonary fibrosis—with no distinction made between systemic and lung-limited illness nor any acknowledgement of the prognostic implications of an acute versus chronic presentation.

In the 1960s authors began to regularly substitute the term *IPF* for *acute diffuse interstitial fibrosis*.[5,6] A debate began concerning the chronicity of this disease, with some authors suggesting a slow course punctuated by "terminal complications,"[5] while others reported an average illness of no more than 2 years.[6]

The term *fibrosing alveolitis* was introduced in England in 1964.[7] *Cryptogenic fibrosing alveolitis (CFA)* became the preferred term for pulmonary fibrosis in the European literature and is essentially synonymous with modern-day IPF. This term was originally meant to improve upon its predecessor by capturing pathologic features in a manner that was more precise and descriptive. CFA refers to the interalveolar location of the inflammation in pulmonary fibrosis as compared with the intra-alveolar inflammation of infectious pneumonia. This interalveolar septal inflammation was dubbed "alveolitis." It was maintained that alveolitis was responsible for the subsequent development of fibrosis, and it was suggested that corticosteroids be used to treat alveolitis to prevent this progression.

The most important advance came in 1964 with the publication of an improved and safe technique for performing open lung biopsy.[8] With this procedure, it became possible to carry out a widespread analysis of lung tissue from patients with suspected pulmonary fibrosis. Before long, there were new insights into the pathology associated with fibrotic lung disease.

In 1969 Liebow and Carrington heralded the modern era of ILD histopathology with the notion that IIP could be further categorized into separate pathologic subtypes. They described distinct patterns of IIP that were identified by examination of lung biopsy specimens with light microscopy. Moreover, these subtypes were found to predict prognosis and response to treatment. Based on their research findings, Liebow and Carrington produced the first detailed histopathologic classification of IIP. They created five categories that were termed *UIP*, *desquamative interstitial pneumonia (DIP)*, *bronchiolitis obliterans interstitial pneumonia (BIP)*, *lymphocytic interstitial pneumonitis (LIP)*, and *giant cell interstitial pneumonia (GIP)*. More recent observations have led to a modification of this classification of IIP subtypes. New categories have been added, such as *respiratory bronchiolitis–associated interstitial lung disease (RB-ILD)* and *nonspecific interstitial pneumonia (NSIP)*.[9,10]

Simultaneously, a revolution in thinking about the pathogenesis of IPF affected the way in which experts talked about the disease. Researchers at the National Heart, Lung, and Blood Institute (NHLBI) were major proponents of an "inflammatory theory" of pathogenesis as originally proposed by European investigators. This theory was based on studies at the NHLBI throughout the 1970s during which excessive amounts of inflammatory cells were identified in bronchoalveolar lavage (BAL) fluid obtained from IPF patients.[11] The NHLBI agreed with European researchers who had coined the term *alveolitis* and the NHLBI also endorsed corticosteroid treatment.

The inflammatory theory has since fallen from favor, mostly as a consequence of corticosteroid inefficacy, and the term *alveolitis* also has fallen out of vogue. A new hypothesis proposes that IPF is the result of heterogeneous alveolar epithelial injury, which is then followed by aberrant repair. This theory emerged from landmark ultrastructural studies performed in the mid-1980s.[12,13] Using electron microscopy, it was discovered that the alveolar epithelial cells were injured in IPF. In addition, foci of subepithelial fibrosis were first described. This concept of injury and repair was modified and expanded upon by subsequent investigators.[14]

In 1997 a modified version of Liebow's pathologic classifications was proposed.[15] The new classification scheme reinforced acceptance of certain categories within the context of an updated understanding of ILD pathogenesis. DIP and UIP were retained but some original categories were discarded and newer entities were recognized, including RB-ILD in the spectrum of smoking-related lung diseases and NSIP as a provisional category.[15,16] This modern pathologic classification became the basis for a consensus statement that finally standardized the nomenclature of ILD and IPF for the first time.

In 2002 a panel of experts convened, sponsored jointly by the American Thoracic Society (ATS) and the European Respiratory Society (ERS). This panel released an official statement for the purpose of providing a new and comprehensive classification of IIP that considered all clinical, radiographic, and pathologic features. The diseases recognized by the 2002 ATS/ERS classification of IIP are IPF, NSIP, cryptogenic organizing pneumonia (COP), AIP, RB-ILD, DIP, and LIP. Further classification of IPF has been undertaken by joint consensus statements of the American Thoracic Society and European Respiratory Society, most recently updated in 2018.[17] These statements attempt to offer strict definitions for each subtype of IIP with practical guidelines for diagnostic purposes. The benefit of attempting to utilize precise definitions is to provide a structure for consistent diagnostic decisions in both clinical practice and research.

Despite the utility of rigorously defining IIP (and IPF), there are several potential pitfalls. For instance, the current classification system relies upon an assumption that each specific IIP is a discrete clinical entity. There has never been validation of this assumption by careful phenotyping and prospective trials. In addition, these definitions are heavily reliant on surgical pathology, suggesting that pathology be considered the "gold standard"; however, evidence shows even expert pathologists can have difficulty agreeing on pathologic classification.[18] This continues to create confusion and difficulty in the diagnosis of IIPs and IPF. Continued refinement of consensus guidelines, greater expertise of clinicians with this condition, and discovery of clinically applicable molecular signatures and biomarkers will lead in the future to further differentiation of the IIPs and a less heterogeneous collection of similar syndromes that are described as IPF.

EPIDEMIOLOGY

Below we discuss the incidence, prevalence, mortality, and risk factors for IPF.

■ Incidence, Prevalence, and Mortality

The incidence and prevalence of IPF have been difficult to ascertain due to variations in case definitions, data source, and collection methods. Frequently, diagnostic medical codes are used, but these do not take into account whether the diagnosis was made according to consensus guidelines nor the level of confidence in the diagnosis. The consensus guidelines regarding diagnosis have evolved in the last decade, further complicating the analysis of trends in incidence and prevalence over time. Heightened awareness of the condition as well as the increasing frequency with which computed tomography scans (of both the chest and abdomen) are acquired and incidentally detect subclinical disease may contribute to reports of rising incidence of IPF.

Estimates of incidence and prevalence of IPF from around the world are derived from large databases of national health or insurance claims, which most often use diagnostic codes to define cases. In several studies, both narrow and broad case definitions have been utilized, leading to wide variations in estimates. In the United States and Europe, the most recent crude estimates of incidence range from 2.7 to 14.6 per 100,00 person-years.[19–21] The estimates of incidence are somewhat lower in South America and Asia, with reported crude estimates of incidence ranging from 1.2 to 4.2 per 100,000 person-years.[22,23] The prevalence of IPF in the United States ranges from 10 to 60 cases per 100,00. As IPF is a disease of aging, the prevalence is higher for each decade of life.[24,25] Mortality is reported from similar sources as incidence and prevalence data. Mortality estimates vary across regions, perhaps due to methods of reporting, and range from as low as 1.2 to 13 per 100,000.[23]

■ Risk Factors

With increasing evidence of various intrinsic and extrinsic risk factors for the development of IPF, whether this disease remains truly "idiopathic" has been debated,[26] but that IPF represents a complex and multifaceted disorder that is a consequence of multiple risk factors is widely accepted. Risk factors can be classified as those intrinsic to the individual—such as biologic sex, senescence, genetic predisposition, and a variety of comorbidities—and extrinsic factors, such as inhaled exposure to tobacco, environmental toxins, and air pollution.

Biologic Sex

IPF is a male-predominant disease across international cohorts. Men account for 65% to 80% of patients in well-phenotyped disease registries from various specialized care centers, national registries, and randomized clinical trials.[27,28] Mouse models of pulmonary fibrosis also show sexual dimorphism, with male mice developing more severe fibrosis than females.[29] Although the basis of the male predisposition has not been definitively established, differential exposure to inhaled toxins due to stereotypically male-predominant occupations or behaviors (e.g., cigarette smoking) have been hypothesized. However, sex-stratified case-control studies of some such exposures suggest that men with exposures are more likely to develop IPF than women. For example, a national case-control study from Finland found that men who smoked and had occupational exposures had twofold higher odds for IPF compared to women with similar exposures.[30] The role of sex hormones and sex-linked genes have not been thoroughly studied in IPF, but they are a plausible means of exploring the sex bias.

Senescence

Epidemiologic studies consistently demonstrate that IPF is a disease of aging. The majority of IPF cases present in the sixth through eighth decades of life, with the average age at time of diagnosis of 66 years. The prevalence of the disease increases nearly twofold with every decade above age 50 years.[24]

While aging on an organismal level is most apparent clinically, aging on a cellular level—cellular senescence—is permissive of progression of pulmonary fibrosis. Whatever the initial insults to the lung may be, senescence reprogramming renders the bronchoalveolar epithelium unable to regenerate, thus allowing a dysregulated response to injury that promotes fibrosis.[26] These changes include a senescent phenotype among lung fibroblasts that favors proliferation and collagen deposition to apoptosis.[31] Additionally, senescent bone-derived mesenchymal stem cells lose the capacity to differentiate and thus participate in lung repair.[32]

Telomeres, the repeating nucleotide sequences found at the end of chromosomes, shorten with each cell cycle division. Once telomeres reach a limit of length, a DNA damage response is activated and leads to cell cycle arrest. In the lung, this translates to an inability of the type II pneumocyte to contribute to repair. As such, shortened telomeres are a marker of cellular senescence. Shortened telomere length in peripheral blood leukocytes and lung tissue of IPF patients—well in excess of that expected for age—have been observed IPF.[33,34] Although some familial forms of IPF are associated with mutations in telomere and telomerase-related genes, shortened telomeres are found even in absence of detectable mutations.

Genetic Factors and Familial Pulmonary Fibrosis Case series of familial pulmonary fibrosis, referred to as *familial interstitial pneumonia (FIP)*, account for <2% of all cases of IPF. FIP is defined by at least two relatives within three degrees of relation presenting with IPF.[35] The largest case series report to date of FIP identified 111 families with 309 total affected members. Transmission was most consistent with an autosomal dominant pattern of inheritance with variable penetrance. This study revealed a mean age at diagnosis of 68.3 years, with a slight male predominance (55%) and an increased association with cigarette smoking, even after controlling for age and gender differences. Phenotypically, there was variation even within families on the pathologic pattern of disease, although the majority of cases (80%) still met the then-contemporary 2011 ATS/ERS joint society diagnostic criteria for probable or definite IPF.[36] More recently, radiographic screening in 105 asymptomatic first-degree relatives of patients with any form of pulmonary fibrosis observed interstitial lung abnormalities in approximately 30%.[37] The risk was similar irrespective of whether the index patient's disease was classified as sporadic or idiopathic.

The identification of familial clusters has led to the search for and discovery of multiple genes associated with risk for IPF. Genome-wide association studies (GWAS) of IPF have identified a number of loci associated with risk for IPF. These include genes that are associated with alveolar instability, activation of the unfolded protein response and apoptosis, early cellular senescence by defects in telomere maintenance, altered host defense, and cell-cell adhesion (Table 54-1).[38] Most of these genetic variants are rare, save for two: the mucin gene *MUC5B* and *TOLLIP*, a regulator of the innate immune response, which are reported to be "common" as defined by minor allele frequency in excess of 5%.[39,40] These data confirm a generally understood concept that there is a combination of genetic factors and environmental exposures that contribute to risk for IPF. That IPF represents a convergence of multiple risk factors, of which genetic predisposition is one part rather than a direct cause, accounts for the significant heterogeneity observed in this disease.

TABLE 54-1 Genes Associated with Risk for IPF

Proposed Mechanism	Consequence of Mutation	Genes
Alveolar instability	Increased endoplasmic reticulum stress	*SFTPC, SFTPA1, SFTPA2*
	Activation of the unfolded protein response	*ABCA3*
	Apoptotic signaling	
Early cell senescence	Telomere shortening	*TERT, TERC*
	Impaired telomere stabilization	*DKC1, TINF2, PARN*
		RTEL1
Altered host defense	Increased mucous accumulation	*MUC5B, MUC2*
	Proinflammatory milieu	*TOLLIP, TLR3, HLA-DRB1,*
	Reduced pathogen recognition	*IL1RN, IL8*
Cell–cell adhesion	Loss of epithelial integrity	*DSP, DPP9*

Inhaled Exposures

Approximately two-thirds of IPF patients report a history of ever smoking cigarettes, but only a small percentage of patients are active smokers by the time of diagnosis.[28,41] A meta-analysis of five case-control studies demonstrated that IPF patients were significantly more likely to report a history of smoking than controls with an odds ratio (OR) of 1.58 (95% confidence interval [CI], 1.27–1.97).[42] Risk may be dose dependent, as Baumgartner et al. reported that IPF patients with a greater than 21-pack-year smoking history had an OR of 2.26 (95% CI, 1.3–2.8) compared to individuals with less than a 20-pack-year history.[43]

Although a causal relationship has not been established, multiple deleterious effects of cigarette smoke that can promote fibrogenesis have been described: in vitro, exposure to cigarette smoke is associated with epithelial-to-mesenchymal transition and transformation to a fibroblast-like phenotype among alveolar type II cells.[44] Various in vivo models of fibrosis have reported that nicotine stimulates epithelial cell release of transforming growth factor beta (TGF-β),[45] a critical protein for fibrosis. Cigarette smoking is also associated with accelerated shortening of telomeres[46] and endoplasmic reticulum stress,[47] both of which favor fibrosis to wound repair in response to injury.

Epidemiologic studies that have linked environmental and occupational exposures to IPF predate the most current classification schema, and a significant portion of these may represent alternate ILD diagnoses, such as hypersensitivity pneumonitis or various pneumoconioses.

Comorbidities

Given the potential for lung injury with recurrent microaspiration of gastric fluids, gastroesophageal reflux (GER) has been implicated in the pathogenesis of IPF, especially given reports of high prevalence in patients with IPF. Hiatal hernias were more common on CT scans of patients IPF compared to those with COPD or asthma in a single center retrospective study.[48] Cross-sectional studies have failed to establish whether IPF is a cause or a consequence of GER. The effect of antiacid therapy on the progression of IPF has been evaluated by causal association studies, but when accounting for the biases of retrospective analysis, proton pump inhibitor therapy does not appear to attenuate the progression of IPF.[49]

Obstructive sleep apnea (OSA) is common in patients with IPF. Estimates of prevalence range from 59% to 88%.[41] The ongoing and increased respiratory efforts made by respiratory muscles in the setting of proximal airway obstruction during apneas and hypopneas occur predominantly at the most peripheral aspects of the lung. The subpleural spaces, especially at the basal aspects of the lungs, are the areas that experience the greatest degree of pleural pressure changes, which can be a stimulus for repetitive alveolar microinjury. Notably, these are the same areas of the lung that are characteristically involved in UIP. Furthermore, serum levels of the glycoprotein KL-6, a marker of lung injury and mortality in IPF, are elevated in OSA. Whether treatment for OSA can alter disease progression or survival in IPF remains unknown.

Microbial Factors

Whether microbes play a role in the predisposition to or pathogenesis of IPF has long been an area of interest. Initially, attention was focused on chronic viral infections, particularly herpesviruses. In one study, 97% of IPF patients tested positive for a herpesvirus (Epstein-Barr, cytomegalovirus, human herpesvirus 7, or human herpesvirus 8) compared with only 37% of controls. Latent infections may be one route for initiation of alveolar epithelial injury early in the pathogenesis of IPF.[50]

More recently, attention on microbial factors has shifted away from latent infections to the role of constituent organisms: the lung microbiome. As with latent infections, different phenotypes of the lung microbiome may be associated with either greater predisposition to lung injury or direct injury from the organisms themselves. While the exact role of microbiome has not yet been well defined, the greater bacterial burden has been reported in the BAL fluid of patients with IPF relative to those with COPD, and different phenotypes of the lung microbiome are associated with progression and survival in IPF.[51] Different genera of bacteria were found to be more prevalent in IPF relative to COPD and chronic hypersensitivity pneumonitis.[51,52]

CLINICAL CHARACTERISTICS

Details of the clinical presentation of IPF and associated laboratory and radiographic findings are considered below.

Clinical Presentation

Patients with IPF typically present with gradual onset of dyspnea on exertion and dry cough. Patients usually have symptoms for more than 6 months before they seek specialized medical care. A multicenter cohort from Germany revealed that participants had a mean symptom duration of 3.7 years prior to diagnosis.[53] The cough is typically nonproductive, although patients may experience phlegm production related to traction bronchiectasis.[54] Other associated symptoms are rare and include weight loss, fatigue, fever, arthralgias, or myalgias. Given the increasing use of computed tomography for other conditions (e.g., lung cancer screening, routine abdominal complaints), asymptomatic patients may also present after incidental radiographic findings that ultimately lead to the diagnosis of IPF.

Physical examination usually reveals fine, bibasilar inspiratory crackles that can extend to the upper lung zones as the disease progresses. Clubbing, a deformation of the nail base resulting in a swollen and convex distal phalanx with loss of the nail fold angle, can be found in up to 50% of patients and is associated with poor prognosis.[55] Physical examination may also aid in identifying an alternate diagnoses to IPF, such as with signs suggestive of connective tissue diseases, including sclerodactyly, Raynaud's phenomenon, synovitis, dermatomyositis, and proximal muscle weakness.

Laboratory Studies

Laboratory studies from blood tests are most useful for identifying alternate diagnoses to IPF. These include autoantibodies for conditions that can present with similar radiographic findings, such as connective tissue diseases; however, low-titer autoantibodies should not necessarily rule out a clinical diagnosis of IPF in absence of other clinical signs and symptoms, especially as autoantibodies are more prevalent in the aging population. Antineutrophil cytoplasmic antibodies, typically associated with pulmonary vasculitis syndromes, can be elevated in IPF. The clinical and radiographic findings of vasculitides vary substantially from IPF, so the two diagnoses are not often in contention in the same differential diagnosis. In patients with a history of environmental exposures suspicious for hypersensitivity pneumonitis, the presence of antigen-specific IgG can support a chronic hypersensitivity pneumonitis over IPF.

Radiology

The conventional chest radiograph is of limited utility in patients with IPF. The most common findings are lower lung zone predominant reticular changes, and occasionally, traction bronchiectasis may be appreciated as well. While the chest radiograph is abnormal in nearly all patients with IPF, up to 10% of patients may have normal appearing films, especially in early stages of the disease. As such, high-resolution computed tomography (HRCT) of the chest is the most sensitive mode for radiographic evaluation of IPF and other ILD.

HRCT differs from conventional non-contrast CT scans of the chest. HRCT allows a detailed examination of the lung parenchyma by creating ≤1.5-mm thin slices of the chest. Typically, ILD protocols include additional expiratory and prone sequences to assess for air trapping and atelectasis, respectively. HRCT uses a computerized reconstruction algorithm to maximize spatial resolution. This generates much improved image clarity such that the specificity of interpretations is increased, interobserver variability is reduced, and the overall accuracy of diagnosis is enhanced. HRCT scanning allows for the earlier diagnosis of IPF and permits the identification of alternate patterns of disease.

The primary role of HRCT in the diagnostic evaluation of ILD is the discrimination of a UIP pattern. The Fleischner Society updated diagnostic HRCT criteria of UIP in 2018 to converge with international joint pulmonary society characterization of UIP[17] into four groups (Table 54-2): the *typical UIP* (UIP in the joint society classification) pattern is defined by subpleural and basal predominant reticulation, traction bronchiectasis, honeycombing, and an absence of alternate features (Fig. 54-1). When all these features are present except honeycombing, the pattern is characterized as *probable UIP*. If the distribution of reticular changes is variable or diffuse or if there is evidence of fibrosis but with inconspicuous features suggestive of a non-UIP pattern, the pattern is described as *indeterminate for UIP*. The final group, classified as *consistent with non-IPF diagnosis* (*alternative diagnosis* in the joint society classification), is based on the presence of radiographic findings that suggest an alternate diagnosis to IPF, such as: upper lung or mid lung predominant distribution of reticulation or bronchiectasis; predominant consolidation; extensive pure ground glass opacities; extensive mosaic attenuation with lobular air trapping; and diffuse nodules or cysts.[56]

The main advantage of an HRCT is in its concordance with surgical lung biopsy findings of UIP: a *typical UIP* pattern on HRCT

TABLE 54-2 Radiographic Classification of UIP

	UIP Typical UIP[a]	Probable UIP	Indeterminate for UIP	Alternative Diagnosis CT Features Most Consistent with Non-UIP Diagnosis[a]
Distribution	Subpleural and basal predominant reticulation; distribution is often heterogeneous	Subpleural and basal predominant; distribution is often heterogeneous	Subpleural and basal predominant *or* Variable *or* Diffuse	• Peribronchovascular • Perilymphatic • Upper or midlung Subpleural sparing
Features	Reticulations and honeycombing with or without peripheral traction bronchiectasis or bronchiolectasis	Reticular pattern with peripheral traction bronchiectasis or bronchiolectasis May have mild GGO in areas of reticulation or honeycombing	Subtle reticulation May have mild GGO or distortion ("early UIP pattern")	Features of another diagnosis including: • Diffuse cysts • Extensive mosaic attenuation • Predominant GGO • Diffuse nodules • Consolidations • Pleural effusions, nodules, or thickening

[a]Fleischner Society terminology for UIP.

UIP, usual interstitial pneumonia; GGO, ground glass opacities.

corresponds to a 90% to 97% agreement with surgical lung biopsy reading of UIP; similarly, a *probable UIP* pattern corresponds to 82% to 94% agreement with a histologic reading of definite or probable UIP from a surgical lung biopsy.[57,58] The concordance between radiographic pattern and histopathologic pattern is poor with *indeterminate for UIP* and *consistent with non-IPF diagnosis (alternative diagnosis for UIP)* patterns. The caveat, however, is that patterns other than *typical UIP* and *probable UIP* do not rule out the possibility of a diagnosis of IPF, as histopathology may still show a well-defined UIP pattern in those cases. In absence of data to suggest an alternate diagnosis, a confident diagnosis of IPF could still be made in the setting of *indeterminate* or *non-IPF* radiographic patterns if typical histopathologic features are present on histopathologic evaluation.

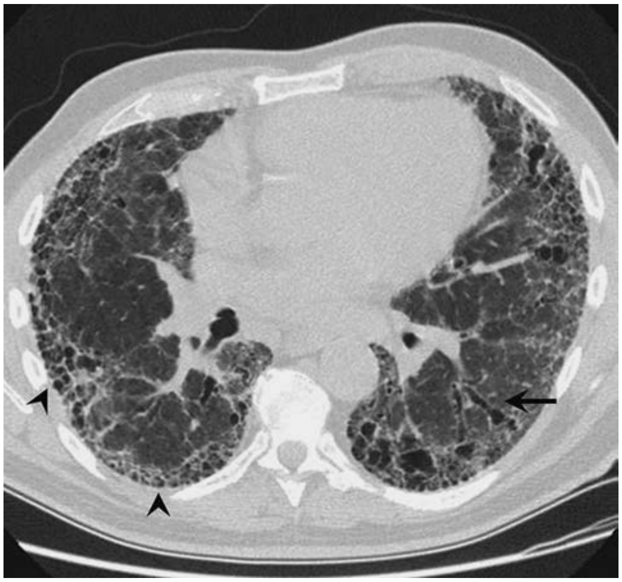

Figure 54-1 Computed tomography scan illustrates the "classic" features of idiopathic pulmonary fibrosis (IPF), the usual interstitial pneumonia (UIP) pattern. Bilateral, peripheral, and subpleural reticular infiltrates are evident. The presence of advanced fibrosis is indicated by honeycomb changes *(arrowheads)* and traction bronchiectasis *(arrow)*. These features permit experienced clinicians to make a confident radiographic diagnosis of IPF.

Pathology

Evaluation of pathologic specimens obtained from surgical lung biopsy and studies procured through bronchoscopy may be helpful in the evaluation of suspected IPF.

Surgical Lung Biopsy

Surgical lung biopsy, most commonly performed as video-assisted thoracoscopic surgery (VATS), is the gold-standard means of sampling lung tissue in the assessment of ILD. A histopathologic pattern of UIP in the absence of alternate history, exam, and laboratory findings (in essence, UIP) can lead to a confident diagnosis of IPF. The histopathologic hallmark of UIP is temporal heterogeneity: areas of dense interstitial collagen deposition, fibroblastic foci, and honeycomb changes alternating with normal lung (Figs. 54-2 and 54-3). Areas of honeycomb cysts are composed of fibrotic air spaces with cystic defects, which are often filled with mucins. The most recent clinical practice guidelines on IPF also classify histopathologic patterns of UIP into the following categories: *UIP*, *probable UIP*, *indeterminate for UIP*, and *alternative diagnosis* (Table 54-3).[17]

While a histologic pattern of UIP is necessary for the diagnosis of IPF, it is not sufficient. As with radiographs, alternate features such as granulomata and lymphoid follicles may be present along with UIP and suggest alternate diagnoses, such as hypersensitivity pneumonitis or connective tissue disease–associated ILD. As with radiographs, histopathologic findings should be correlated with HRCT pattern, history, physical examination, and other data in the context of a multidisciplinary discussion to establish a diagnosis of IPF.

Bronchoscopy

Bronchoscopic evaluation plays a limited role in the diagnosis of IPF. Bronchoalveolar lavage (BAL) fluid is typically unhelpful in

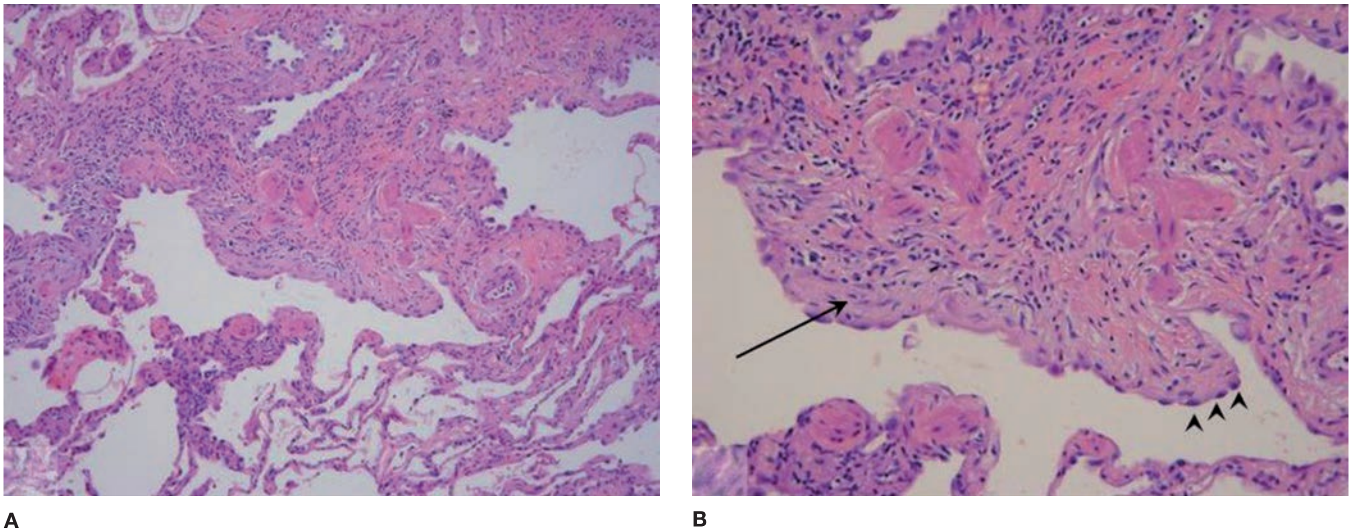

Figure 54-2 **A.** Low-magnification photomicrograph of usual interstitial pneumonia (UIP) showing the characteristic heterogeneous involvement of the parenchyma. Zones of interstitial fibrosis are seen alternating with areas of normal lung. **B.** Higher magnification demonstrates enlarged cystic air spaces lined with hyperplastic alveolar epithelium *(arrowheads)*. Beneath the mucosal layer is an advancing region of young fibrosis containing loose extracellular matrix *(pale pink staining)* and fibroblasts *(arrow)*.

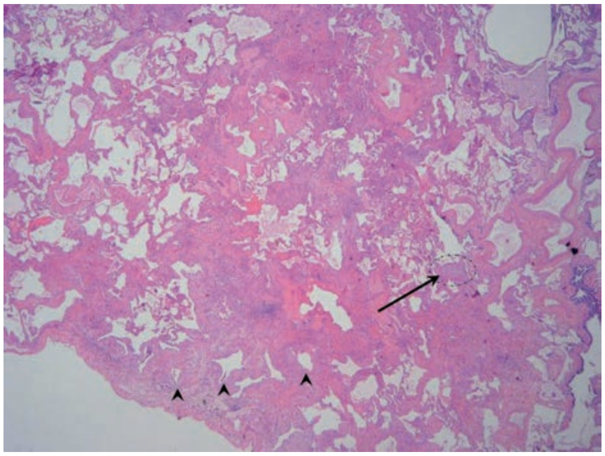

Figure 54-3 Scanning view of usual interstitial pneumonia (UIP) demonstrates the characteristic variegated appearance of UIP. Note the honeycomb change *(arrowheads)* present in the region of dense fibrosis adjacent to the pleural surface. A fibroblast focus *(arrow)* is seen at the leading edge of advancing fibrosis.

the diagnosis of IPF, but in cases of UIP in which the major differential diagnosis is that of chronic hypersensitivity pneumonitis, a lymphocytic predominance can suggest the latter diagnosis over the former. Conventional transbronchial biopsies are of insufficient size to determine the temporal heterogeneity that defines UIP. The role of transbronchial lung cryobiopsy in diagnosing UIP has not been evaluated with a large sample size. A wide range has been reported regarding agreement between surgical lung biopsy and lung cryobiopsy (20% to 70%).[59,60] There is clinical equipoise regarding its use in the diagnostic algorithm of IPF.

Given the insufficient tissue biopsy size to assess for UIP with transbronchial biopsies, and concern for perioperative complications with surgical lung biopsy in a generally older patient population with more comorbidities, a molecular signature for UIP has long been sought. Recently, a machine learning algorithm derived and validated a molecular classifier for UIP from transbronchial biopsy samples, using histopathologic diagnosis of UIP from surgical lung biopsy and lung cryobiopsy samples as the references.[61] A subsequent validation study in 96 patients reported a sensitivity of approximately 60% and specificity of approximately 92%.[62] Although the use of this molecular classifier has not yet been

TABLE 54-3 Histopathologic Classification of UIP (from Surgical Lung Biopsy)

UIP	Probable UIP	Indeterminate for UIP	Alternative Diagnosis
Dense fibrosis with architectural distortion (i.e., destructive scarring and/or honeycombing) Predominant subpleural and/or paraseptal distribution of fibrosis Patchy involvement of lung parenchyma by fibrosis Fibroblast foci Absence of features to suggest an alternate diagnosis	Some histologic features from column 1 are present but to an extent that precludes a definite diagnosis of UIP/IPF *And* Absence of features to suggest an alternative diagnosis *Or* Honeycombing only	Fibrosis with or without architectural distortion, with features favoring either a pattern other than UIP or features favoring UIP secondary to another cause Some histologic features from column 1, but with other features suggesting an alternative diagnosis	Features of other histologic patterns of IIPs (e.g., absence of fibroblast foci or loose fibrosis) in all biopsies Histologic findings indicative of other diseases (e.g., hypersensitivity pneumonitis, Langerhans cell histiocytosis, sarcoidosis, LAM)

Data from Raghu G, Remy-Jardin M, Myers JL, et al. Diagnosis of Idiopathic Pulmonary Fibrosis. An Official ATS/ERS/JRS/ALAT Clinical Practice Guideline. Am J Respir Crit Care Med. 2018;198(5):e44–e68 formally incorporated into the diagnostic algorithm of UIP across professional societies or working groups for the diagnosis of IPF, its development has been the first to deliver on the promise of less invasive means of ascertaining a histopathologic pattern of UIP.

■ Diagnostic Algorithm

Given that the natural course and treatment of IPF varies from other ILD in its prognosis and treatment, it is imperative to ascertain a confident diagnosis. Similarly, in the clinical research setting, minimizing heterogeneity is important to establish efficacy of investigational drugs in a disease that is more driven by fibrosis rather than inflammation. Given significant interobserver variability between pulmonologists, radiologists, and pathologists when assessing a clinical scenario independently, a multidisciplinary approach has improved agreement. Although society practice guidelines advocate for a multidisciplinary approach to diagnosis, the necessary specialty expertise and format of the approach has not been specifically described.

The diagnostic algorithm (Fig. 54-4) relies on history to exclude non-IPF etiologies, such as those associated with underlying connective tissue disease, culprit drug exposure, or environmental exposures. Laboratory studies are usually pursued to evaluate for otherwise occult autoimmune disease. If there are no clear triggers for the ILD, then HRCT features are examined next. If there is a *typical UIP* pattern, then that is sufficient to make a diagnosis of IPF. However, if the radiographic pattern is not that of *typical UIP*, then a multidisciplinary discussion is recommended to evaluate for candidacy for lung biopsy. If the histopathologic pattern does not show UIP, or if a biopsy cannot be safely performed for whatever reason, then the multidisciplinary discussion itself would yield a clinical diagnosis, albeit of lesser confidence.

■ Pulmonary Physiology

Complete pulmonary function tests including spirometry, lung volumes, and diffusing capacity of the lung for carbon monoxide

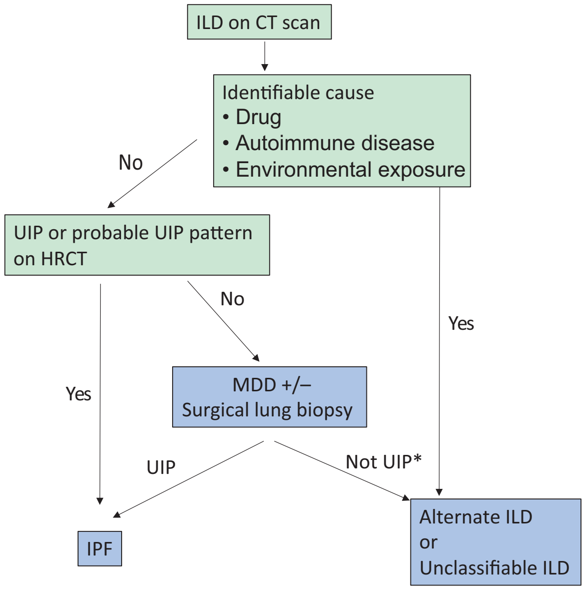

Figure 54-4 The diagnostic algorithm for IPF per joint professional society guidelines depends on the presence of an HRCT UIP pattern—in the absence of history, physical examination, or laboratory findings to suggest an alternate diagnosis—to establish a diagnosis of IPF. In cases of non-UIP patterns on HRCT, multidisciplinary discussion should take place to determine whether surgical lung biopsy is an option after accounting for the individual patient's risk for perioperative complications. IPF, idiopathic pulmonary fibrosis; MDD, multidisciplinary discussion; UIP, usual interstitial pneumonia. *Not UIP or no surgical lung biopsy performed.

(DL_{CO}) should be obtained in all patients being evaluated for IPF to gauge severity of disease. In IPF, pulmonary function tests usually identify a restrictive ventilatory defect as evidenced by a symmetrically reduced forced vital capacity (FVC) and forced expiratory volume during the first second of exhalation (FEV_1). Lung volumes are proportionally reduced. The reduced total lung capacity (TLC) and residual volume (RV) are indicative of reduced compliance. As such, the RV/TLC ratio is often normal unless there is a coexisting obstructive pathology, which occurs more frequently in smokers. The presence of a reduced DL_{CO} demonstrates an impairment in gas exchange. A reduction in diffusing capacity may precede the abnormal FVC and lung volumes. IPF can lead to pulmonary hypertension, which is also associated with a reduced DL_{CO}.

Depending on the severity of gas exchange abnormality, arterial blood gases may show a decreased Pa_{O_2} and chronic respiratory alkalosis. Patients with IPF have tachypnea and often develop a pattern of rapid-shallow breathing. The work of breathing is increased in IPF, especially in later stages. While no chemical changes can explain the observed hyperventilation, the leading theory is that rapid respiratory rates are secondary to altered mechanical reflexes resulting from an increase in elastic recoil and elastic load.

■ Natural History and Prognosis

Across the world, national registries and clinical trials of IPF describe a median survival of 3 to 5 years from time of diagnosis, which may already be several years after the onset of symptoms given known delays in IPF diagnosis. How long the disease is present in its subclinical phase, however, remains unknown. Community-based cohorts report that interstitial lung abnormalities (ILA), a subclinical radiographic phenotype of ILD, are present in 7% to 10% of such cohorts, and a subset of these do exhibit a radiographic pattern of UIP.[63–65]

Although a progressive decline in lung function is the rule in IPF, the time course of the decline is highly variable. In general, patients can exhibit a slow progression, rapid progression, as well as periods of stability punctuated by sharp declines, termed *acute exacerbations*. Any individual patient's trajectory may evolve over time from one progressive phenotype to another.

Acute Exacerbations

Acute exacerbations of IPF (AE-IPF) are episodes of sharp decline in lung function. AE-IPF are defined by an acute worsening in symptoms and/or physiology usually occurring over about a month or less that is matched by radiographic findings of new bilateral ground glass infiltrates on the background UIP pattern. Decompensation solely due to cardiogenic pulmonary edema needs to be excluded. AE-IPF may occur in the context of a clear trigger, often viral infections, but may be idiopathic events as well. Regardless of the cause, AE-IPF are associated with high morbidity and mortality. AE-IPF tend to occur in patients with more advanced disease and worse physiology, and can lead to dramatic increase in supplemental oxygen requirement, decrease in functional status, and even death. The estimated median survival after AE-IPF is approximately 3 months.[66]

Histopathologic examination of AE-IPF commonly reveals a UIP pattern with superimposed diffuse alveolar damage (DAD) characterized by diffuse alveolar septal thickening within a pale matrix that includes hyaline membranes and fibrin. UIP with superimposed organizing pneumonia has also been reported in AE-IPF. AE-IPF typically occurs in patients with established IPF; however, it has been recognized that AE-IPF can be the initial presentation of IPF as well, mimicking AIP.

There are no consensus guidelines on the management of AE-IPF. However, a recent international survey of expert pulmonologists revealed that the vast majority of practitioners administer steroids, and that a majority also initiate antifibrotic medications.[67] The response to either of these medication classes has not been prospectively evaluated, and retrospective studies in this disease state have fundamental biases that limit evaluation of efficacy.

Prognostic Factors

Across all IIP, a radiographic or histopathologic pattern of UIP is associated with worse survival. Since UIP is an integral part of the diagnosis of IPF, it is no surprise that IPF has the worst prognosis of the various IIP.

To counsel patients and to inform clinical decision-making, such as appropriate timing for lung transplantation, an ability to prognosticate survival is helpful in the management of IPF. Increasing age, male sex, and lower physiology are known risk factors for mortality in IPF. The GAP (Genders, Age, Phsyiology) index is a prognositcation tool that classifies patients into one of three stages, each of which corresponds to a different estimated 1-year mortality.[68]

Rather than static measures, changes in pulmonary function over time have been more clearly correlated with measures of long-term survival. For instance, a 10% decline in FVC over 6 months, or a 15% decline in $\mathrm{DL_{CO}}$ over 6 months, predicts shortened survival.[69,70] In clinical practice, at the present time, the use of decrements in pulmonary function remains an important objective means of assessing clinical disease progression.

PATHOGENESIS

IPF is a complex disorder with myriad pathways that contribute to its pathogenesis. Rather than a single common pathway that results in the IPF phenotype, a combination of multiple factors leads to epithelial cell injury and dysfunction, aberrant wound healing, and progressive fibrosis. There have been sufficient discoveries since the term *idiopathic pulmonary fibrosis* was first used in 1948 to challenge the veracity of the *idiopathic* moniker.[26] The modern understanding of IPF pathogenesis includes an understanding of (1) the risk factors that predispose individuals to disease; (2) the primary role of the lung epithelium as the site of disease activation and perpetuation, with endoplasmic reticulum stress promoting increased cell turnover faced with the challenge of senescence reprograming to limit the capacity for repair and regeneration; (3) the dominance of fibroblast activation and myofibroblastic differentiation to promote the progression of fibrosis that is the hallmark of IPF.[26] The IPF alveolar epithelium is likely vulnerable due to a combination of age-related and genetic factors. An accumulation of growth factors in IPF may originate from the persistent proliferative response of epithelial cells. A downstream consequence of “frustrated” epithelial cell regeneration is recruitment of fibroblasts and myofibroblasts through the release of such growth factors. In essence, the signal to recruit and maintain a pool of mesenchymal cells (fibroblasts) might originate from an inability to successfully re-epithelialize the alveolar lining surface.

Great strides are constantly being made to elucidate the mechanisms of IPF pathogenesis.[71,72] Some recent advances to highlight include increasingly larger GWAS that confirm previously identified genetic associations and identify new risk loci[73] and the leveraging of single cell technologies to better understand the unique cellular makeup of the IPF lung, to identify novel cell types (the ionocyte),[74] and to better understand the diversity and function of known cell types in IPF to widen the field for possible therapeutic targets in this disease.

■ Alveolar Epithelium

Examination of tissue from patients with IPF has confirmed an irregular pattern of alveolar epithelial cell proliferation, concurrent with dysregulation of proteins that control the cell cycle.[75,76] Multiple lines of investigation suggest that epithelial cells are critically involved in the pathogenesis of IPF.[77,78] The prevailing hypothesis is that repetitive low-level injury to a vulnerable or susceptible alveolar epithelium drives the pathologic features of IPF.[72] The source of epithelial injury, and whether it is endogenous or exogenous, remains a mystery.

Epithelial Apoptosis and Injury

An emerging body of literature supports alveolar epithelial cell injury and apoptosis as important features of IPF and in the development of experimental pulmonary fibrosis. Electron microscopic studies of human IPF tissue demonstrate injury and apoptosis of alveolar epithelial cells.[13] BAL from patients with IPF has established the presence of proapoptotic proteins.[79] In the bleomycin model of lung injury and fibrosis in animals, fibrosis can be abrogated by various approaches to inhibit epithelial cell apoptosis.[80–82] These include a reduction in experimental fibrosis by inhibiting the Fas–Fas ligand pathway, angiotensin production, or caspase activation.

In addition to direct inhibition of apoptotic pathways, factors that cause epithelial cell apoptosis are critical to the development of fibrosis. Evidence suggests that fibroblasts produce angiotensin peptides that lead to epithelial apoptosis. Other researchers have demonstrated that TGF-β is involved with promoting epithelial cell apoptosis.[83] Oxidant injury also may promote epithelial cell death, and several studies of IPF patients have confirmed excessive oxidant production as well as glutathione deficiency.[84–86] Tumor necrosis factor alpha (TNF-α) has been shown to promote alveolar epithelial cell apoptosis in vitro.[87] In a mouse model, knockout of the TNF-α receptor confers resistance to bleomycin-induced lung fibrosis, while overexpression of TNF-α in the mouse has been associated with an increase in experimental fibrosis.[88] Patients with IPF are known to exhibit an exaggerated expression of TNF-α, which may contribute to epithelial injury.[89]

Evidence of direct injury to the alveolar epithelium suggests that this may be an important model of pulmonary fibrosis. Utilizing a transgenic mouse directing expression of human diphtheria toxin receptor in surfactant protein C (SPC)-expressing cells, it was shown that targeted injury of alveolar type II (AT2) epithelial cells resulted in the development of experimental lung fibrosis.[90] The development of fibrosis in this targeted epithelial cell injury is dependent on plasminogen activating factor 1 and the recruitment of monocytes and macrophages into the lung.[91,92]

Alveolar Type II Cell Dysfunction

In addition to epithelial cell depletion, alveolar injury also drives epithelial cell dysfunction, particularly in the AT2 cell. While AT2 cells are plastic, they do not directly transform into mesenchymal cells. However, they are able to and do acquire a profibrotic phenotype that promotes the expansion of fibroblasts, the activation of myofibroblasts, and extracellular matrix deposition.[93]

Alveolar Type II Progenitor Cell Function in IPF

A subset of AT2 cells serve as progenitors to replete alveolar type I (AT1) cells.[94] State-of-the-art lineage labeling in the adult mouse demonstrated that AT2 cells can regenerate over time.[95] Thus, AT2 cells are stem cells in the alveolar space. A significant development in exploring the regenerative capacity of AT2 cell has been the employment of “alveolospheres” as in vitro organoid assays where AT2 cells can be cultured with fibroblasts in Matrigel and form alveolar-like structures.[95] Single cell analysis from several groups has clearly demonstrated that there is a loss of AT2 cells in IPF.[96–98] Interestingly, there is an expansion of basal cells. Recently it has been demonstrated that IPF AT2 cells have reduced regenerative capacity in organoid assays.[99] Mechanisms that can restore the regenerative capacity of IPF AT2 cells are being actively pursued and offer important new therapeutic approaches in IPF.[99,100]

Progenitor-capable AT2 cells reside next to fibroblasts and represent niches wherein juxtacrine Wnt signaling by fibroblasts maintains this pool of AT2 stem cells.[101] However, autocrine activation of Wnt signaling *within* AT2 cells prevents their reprograming into AT1 cells, whereas in vitro blockade of Wnt signaling in AT2 cells permits their transdifferentiation into AT1 cells.[101] These data fill the gap in knowledge of the mechanism by which long-observed upregulated Wnt signaling in AT2 cells promotes pulmonary fibrosis.[102]

Basal Cell Aberrations

In the pseudostratified respiratory epithelium, basal cells reside adjacent to the basement membrane and serve as progenitor cells. In IPF and other chronic lung diseases, expansion of basal cell populations has been observed.[103] In the normal lung, basal cells are functionally heterogenous and include subtypes that are multipotent and secretory-primed. Recently, however, single cell RNA sequencing has identified that secretory-primed basal cells dominate in IPF, and that they are found in abundance in mucin-rich areas.[104] The derivation and validation of a BAL signature that predicts mortality in IPF found that the genes associated with mortality were expressed in airway basal cells,[103] highlighting that basal cells and their derangements may be an important target for future treatments.

Endoplasmic Reticulum Stress

Mutations of surfactant proteins A2 and C have been associated with familial types of pulmonary fibrosis and suggest a potential genetic mechanism for alveolar epithelial injury.[105–110] In alveolar epithelium, during both homeostatic and inflammatory conditions, surfactant proteins are regularly produced. This production requires appropriate and coordinated folding and packaging of the proteins in the endoplasmic reticulum (ER) prior to their release.[111] When this folding does not occur correctly, the cell experiences ER stress, which results in activation of the unfolded protein response (UPR)—a cellular pathway designed to limit the deleterious consequences of misfolded proteins.[112] The fact that mutations in these proteins were associated with pulmonary fibrosis suggested that misfolding of these proteins could result in cellular stress and thereby enhance the vulnerability of the epithelium.[113] Using a mouse model that expressed a mutant form of SPC, Lawson et al.[114] demonstrated that misfolded SPC caused ER stress and thereby activating the UPR. Despite this activation the mice did not spontaneously develop pulmonary fibrosis but rather required a secondary challenge with bleomycin or viral infection.[114,115] With secondary challenge, the mice exhibiting enhanced ER stress were more susceptible to fibrosis. A growing body of literature suggests that the UPR response is defective with advancing age, which may provide a direct link to IPF as it is a disease of advanced age. ER stress and secondary insults provide an attractive model for IPF, as this model system has the potential to link both genetic- and age-related disease factors to microinjuries and a vulnerable epithelium.

■ Fibroblast Biology

The hallmark of pulmonary fibrosis is the development and expansion of scar tissue in the lung. In this context, patients develop progressive respiratory failure associated with unrelenting accumulation of extracellular matrix in the gas-exchanging regions. It is generally accepted that the predominant sources of matrix are fibroblasts. In IPF, fibroblasts accumulate in areas of advancing fibrosis and are associated with regions of alveolar epithelial hyperplasia, called fibroblast foci. Greater numbers of fibroblast foci within lung biopsies correlate with a worse prognosis in IPF.[116,117]

Myofibroblasts

One of the hallmarks of IPF pathology is the development of a subset of cells called myofibroblasts.[118] Much attention has been focused recently on the role of the myofibroblast in the pathogenesis of IPF. The defining characteristics of myofibroblasts are positive staining for α-smooth muscle actin (α-SMA) and production of new collagen. Myofibroblasts have contractile properties critical to normal wound healing, although they appear only transiently in the normal repair process.[119] By contrast, the constitutive presence of myofibroblasts and ongoing deposition of extracellular matrix is characteristic of IPF. In IPF lung biopsies, myofibroblasts have been described in abundance especially in the fibroblastic foci.[120] Myofibroblasts have also been shown to accumulate in bleomycin-induced lung fibrosis. Immunohistochemical studies have suggested that they are important in the production of newly synthesized collagen.[121]

The source of fibroblasts has been a subject of intense research and debate. Several possibilities include resident lung fibroblasts, bone marrow progenitors called fibrocytes, and epithelial cell transition in a process called epithelial to mesenchymal transition (EMT). Evidence has accumulated over the past several years to suggest that bone marrow–derived cells may contribute to the pool of lung fibroblasts in IPF. In an animal model of experimental lung fibrosis it was shown that fluorescently tagged bone marrow–derived cells trafficked to the lung where they became a source of collagen expression.[122] Interestingly these bone marrow–derived cells did not express α-SMA, nor did they express α-SMA when stimulated in vitro with TGF-β, suggesting that they are not capable of acquiring the myofibroblast phenotype. Another group of researchers observed that a newly defined cell type called fibrocytes migrated into the lungs of animals following bleomycin injury.[123] Fibrocytes are a recently recognized cell type of hematopoietic origin that circulate in the peripheral blood and have been suggested to play a role in wound repair.[124] They also have been implicated in the pathogenesis of hypertrophic scars, scleroderma, and asthma-related airway fibrosis.[125] Fibrocytes are present in the blood of patients with IPF and appear to be a marker of disease progression.[145] Still, the exact role of these cells (and their relationship to the fibroblast) remains unclear due to the lack of specificity in lineage-tracing markers.

Another possibility is that the fibroblasts in IPF are derived from the alveolar epithelium. A transformation of cell type from epithelium to mesenchyme is a well-documented phenomenon that takes place during embryogenesis and in cancer. In culture, it has been shown that isolated AT2 cells exhibit a loss of AT2 markers and express fibroblast markers when stimulated with TGF-β, a critical fibrogenic factor. Whether this occurs in IPF remains a point of controversy, with some studies demonstrating colocalization of AT2 and fibroblast markers[126] and others that do not observe evidence of this phenomenon.[127] To address this question in vivo, lineage-tracing experiments were performed. Initial studies utilized a fragment of the human SPC promoter to drive the expression of a lineage label to track AT2 cells.[128,129] Tracking AT2 cells after TGF-β or bleomycin exposure suggested that these cells were a significant source of mesenchymal cells in experimental lung fibrosis. In contrast to these observations, alternative in vivo lineage tracing using a knock-in allele of the SPC gene directing inducible expression of a fluorescent lineage tag in mature AT2 cells did not demonstrate evidence of EMT after bleomycin.[130] This work suggested a complex and heterogeneous proliferation of mesenchymal cells in experimental lung fibrosis. None of the cells that they explored appeared to be the origin of myofibroblasts.[130] Determining the origin of these cells remains an area of active investigation.

Fibroblast Phenotypes and Functions in IPF

Various growth factors that influence fibroblast function have been shown to be produced in the lung tissue of patients with IPF and also shown to mediate the pathogenesis of experimental fibrosis.[131,132] Examples include keratinocyte growth factor, TGF-β, insulin-like growth factor 1 (IGF-1), platelet-derived growth factors (PDGF-A and PDGF-B), fibroblast growth factor 2, and hepatocyte growth factor. Many of these growth factors activate tyrosine kinase signaling pathways that promote fibroblast proliferation and matrix production.

TGF-β is a critical mediator of lung fibrosis in animal models.[133] Several studies have shown that antagonizing TGF-β prevents the development of lung fibrosis.[134] Alternatively, targeted overexpression of TGF-β has been shown to produce progressive pulmonary fibrosis.[135] Evidence suggests that TGF-β has the capacity to promote epithelial cell transformation into a mesenchymal phenotype.[126] Studies have suggested that fibrosis is attenuated in the setting of targeted loss of TGF-β signaling in epithelial cells[136,137] and that epithelial expression of the integrin $\alpha\nu\beta6$ responsible for the activation of latent TGF-β is also critical to the development of fibrosis.[138] TGF-β also induces the differentiation of fibroblasts to myofibroblasts.[139,140] This effect appears to be dependent on NADPH oxidase 4.[141]

Secreted factors that influence fibroblast migration may also be important to fibrogenesis. The production of CXCL10 by innate immune cells may be critical to fibroblast migration and fibrogenesis.[142–144] Recent work highlighted lysophosphatidic acid (LPA) as an additional chemotactic factor for fibroblasts.[144] LPA interacting with its cognate receptor LPAR1 is critical for recruitment of fibroblasts. LPA was increased in the BAL fluid from IPF patients, and inhibition of LPAR1 markedly attenuated the migration of fibroblasts to IPF BAL fluid.

It appears that IPF fibroblasts have an enhanced proliferative capacity compared with non-IPF fibroblasts.[145,146] The mechanism of enhanced proliferation is not fully elucidated, but data suggest that several pathways may be involved. These include defective fibroblast/extracellular matrix interactions, aberrant activation of PI3 K/Akt/S6K1 signaling pathways, and genome-wide derangements in translation control.[147–150] The derangements in transcriptional control have the potential to allow IPF fibroblasts to circumvent normal negative feedback signals that would inhibit fibroblast proliferation and therefore limit fibrogenesis.

While cancer and pulmonary fibrosis are distinct pathologic processes, there is no doubt on the overlap in the phenotype and behavior of fibrotic lung mesenchymal cells and cancer cells, including evasion of cell death and growth suppressors, disease-promoting inflammation, and local invasion.[151] The importance of fibroblast capacity to invade matrix was also demonstrated in mice where there was deletion in regulators of G protein–coupled receptor functioning called β-arrestins. β-Arrestin null mice were protected from experimental fibrosis, and both mouse and IPF fibroblasts had suppression of fibroblast invasion when β-arrestins were inhibited.[152] Such an invasive capacity might lead to the destruction of the basement membrane and collapse of alveolar tissue, both hallmarks of IPF pathology. In an in vitro model, IPF fibroblasts were observed to spontaneously invade an artificial matrix.[153] It was also shown that targeted overexpression of hyaluronan synthase 2, an enzyme that produces the extracellular matrix glycosaminoglycan hyaluronan in myofibroblasts, resulted in enhanced invasive capacity and progressive fibrosis.[154] A subset of IPF fibroblasts have been shown to be invasive and, when instilled into immune-deficient mice in a humanized model of IPF, migrated to the lung and caused fibrosis. Unexpectedly, single cell RNA sequencing of invasive IPF fibroblasts identified an upregulation of the immune checkpoint ligand CD274, also known as the programmed death ligand 1 (PD-L1). PD-L1 was shown to be necessary for the invasive phenotype of IPF fibroblasts in the humanized model.[155] In these studies, the invasive capacity of human IPF fibroblasts could be abrogated by blockade of CD44 (the receptor for hyaluronan), inhibition of hyaluronan synthase 2 (the enzyme responsible for hyaluronic acid production), or inhibition of PD-L1, suggesting that targeting invasive fibroblasts could be a novel therapeutic approach for IPF. As PD-L1 drugs already exist in the clinical space and are widely used for the treatment of various cancers, there is rationale for their study in a clinical trial for IPF.

TREATMENT

The management of patients presents several challenges, namely whom to treat, when to treat, and how to select treatment. In the past decade, new targets for treatment have been identified and agents that inhibit cytokines, proteases, oxidants, and mesenchymal growth factors have been developed. The current treatment axis has two objectives: slow progression of fibrosis and manage symptoms. To achieve this there are pharmacologic and nonpharmacologic strategies, which we describe below.

■ Disease-Focused Therapy

Disease-focused therapies include antifibrotic medications, pulmonary vasodilators, and corticosteroids, as discussed below.

Antifibrotic Medications

Two antifibrotic therapies have been approved for the treatment of IPF: nintedanib and pirfenidone. The efficacy of these medications in slowing the progression of fibrosis is similar and modest. Both medications are associated with significant side effects that may limit tolerance and prolonged use.

In vitro studies demonstrated that nintedanib inhibits signals mediated by multiple receptor and nonreceptor tyrosine kinases, which ultimately leads to the inhibition of fibroblast growth factors that are involved in recruitment, proliferation, and differentiation of fibroblasts, as well as deposition of extracellular matrix.[156] The efficacy and safety of nintedanib was compared against placebo in three large, randomized, controlled, phase 2 and 3 trials (TOMORROW, INPULSIS-1, INPULSIS-2). The studies demonstrated a significant reduction of the rate of decline in FVC after 52 weeks of follow-up when compared with placebo. The most frequent side effect was diarrhea, occurring in more than 60% of the participants who received nintedanib.[157] On the basis of these trials, nintedanib was approved for use in IPF in the United States.

Pirfenidone reduces fibroblast proliferation and collagen production stimulated by TGF-β, but the exact mechanism is unknown.[158] Two large international clinical trials have evaluated the safety and efficacy of pirfenidone. In the first phase 3 multinational CAPACITY 004 trial, pirfenidone was associated with a significant reduction in the rate of decline of FVC; however, the validation study CAPACITY 006 failed to reach significance.[159] A subsequent clinical trial, ASCEND, demonstrated that pirfenidone was associated with a significant reduction in the proportion of patients who had a decline of 10% or greater in their predicted FVC and improved progression-free survival when compared with placebo.[160] In a combined analysis of the ASCEND and CAPACITY trials, pirfenidone was associated with a decrease in both all-cause and IPF-related mortality, which led to the approval of pirfenidone in patients with IPF in the United States.[161]

Pulmonary Vasodilators

The parenchymal architectural distortion in patients with idiopathic pulmonary fibrosis can lead to abnormalities of the pulmonary vasculature and physiology. These changes can lead to precapillary pulmonary hypertension. Sildenafil is a phosphodiesterase inhibitor that leads to pulmonary vasodilation when administered systemically. A double-blind clinical trial in patients with IPF and pulmonary hypertension did not show a statistically significant benefit in walk distance, dyspnea, or patient-reported quality of life.[162] Another trial aimed to study riociguat, a soluble guanylate cyclase stimulator, and was stopped prematurely due to serious adverse events and increased mortality.[163]

The findings in these studies suggested that therapies for pulmonary hypertension in patients with idiopathic pulmonary fibrosis should aim to induce vasodilation in well-ventilated lung areas to avoid exacerbating ventilation–perfusion mismatch, which may worsen outcomes. A more recent clinical trial studied the effect of inhaled treprostinil, an analog of prostacyclin. The investigators reported an increase in 6-min walk distance by a median of 31 m in the study arm relative to controls.[164]

Corticosteroids

Over the past two decades, the role of corticosteroids in patients with idiopathic pulmonary fibrosis has dramatically changed. Current guidelines recommend against the use of corticosteroids as maintenance therapy based on the results of the PANTHER-IPF trial, which observed increased mortality and hospitalization rate in patients who were treated with prednisone, azathioprine, and N-acetylcysteine.[165]

The role of steroids in acute exacerbations of IPF remains unclear. No randomized controlled trials have been reported in this area, and the evidence is anecdotal and based on expert opinion. The rationale behind using steroids in acute exacerbation is suppression of cellular and humoral immunity and reduction of acute inflammation.[166] Based on the limited available data, current guidelines recommend the use of corticosteroids in acute exacerbation, but the recommendation is weak, and the appropriate dose, route, and duration of therapy remain unknown.[167]

Other Pharmacotherapies

As mentioned previously, the treatment of IPF has recently changed. First-line treatment is now antifibrotic medications that are effective at slowing down the rate of FVC decline. In addition to this, large multicenter clinical trials (described below) proved the lack of benefit of other treatment options previously used.

High-dose N-acetylcysteine (NAC), a precursor of glutathione, was studied against placebo in the IFIGENIA trial in addition to prednisone and azathioprine. The study showed a preservation of FVC and $D_{L_{CO}}$, but the study was underpowered due to a high drop-out rate.[168] Subsequently, a study within the PANTHER-IPF cohort compared NAC to placebo and revealed no significant benefit in the preservation of FVC.[169]

The effect of interferon γ-1b was studied in the INSPIRE trial. At the second interim analysis, the study showed no improvement in survival in the treatment arm. As such, the study was stopped earlier than planned.[170]

The PANTHER-IPF trial aimed to determine the safety and efficacy of azathioprine, prednisone, and NAC, a combination frequently used to treat IPF in the past. The study was stopped prematurely after an interim analysis showed that the patients receiving prednisone, azathioprine, and NAC had a higher rate of death when compared with placebo.[165]

GER is commonly found in patients with IPF. GER is associated with cough, and it is believed that chronic micro-aspiration could be a contributor to the progression of IPF. Current IPF treatment guidelines provide a weak recommendation to treat GER regardless of the presence of symptoms.[167] Antiacid therapies such as second-generation antihistamines and proton pump inhibitors (PPI) have been used as a potential therapy. The data on the effect of antiacid medication is mixed. Previous studies have showed an association between antiacid medication and survival[171,172] as well as decreased rate of FVC decline; however, subsequent reanalyses have suggested that the immortal time bias accounted for these differences. Most recently, a large cohort study did not find any difference in all-cause mortality, respiratory related mortality, or respiratory-related hospitalizations in patients who received PPIs compared with those who did not. To date, there have not been any randomized controlled trials that have studied the use of antiacid medications in patients with IPF.[49]

Lung Transplantation

Lung transplantation is a life-saving and life-prolonging therapy for idiopathic pulmonary fibrosis. Patients with significant lung function decline, those with oxygen dependency, and those whose posttransplant life expectancy exceeds their current life expectancy without transplant stand to benefit from transplantation.[173] To aid providers, the International Society of Heart and Lung Transplantation (ISHLT) has established criteria for referral and listing of patients with interstitial lung disease. These criteria include histopathologic or radiographic evidence of UIP or NSIP, FVC less than 80% predicted or $D_{L_{CO}}$ of less than 40% predicted, any oxygen requirement, and any dyspnea or functional limitation attributable to lung disease.[174] Absolute contraindications for lung transplant are malignancy in the last 2 years, advanced dysfunction of another organ, nonadherence, lack of social support, and substance addiction. Age older than 65 years old is a relative contraindication.

Supplemental Oxygen

The use of supplemental oxygen for resting hypoxemia in ILD is extrapolated from studies in patients with chronic obstructive pulmonary disease (COPD).[175] The clinical practice guidelines for IPF make a strong recommendation for the use of supplemental oxygen with resting saturation below 88%, severe resting hypoxemia ($Pa_{O_2} \leq 55$ mm Hg) or moderately severe resting hypoxemia ($Pa_{O_2} \leq 60$ mm Hg), as well as with complications of chronic hypoxemia (cor pulmonale, polycythemia).[167] A recent study showed that in patients with IPF with exercise-induced hypoxemia, supplemental oxygen during exercise improved the endurance time, desaturation, and subjective symptoms compared with placebo.[176]

■ Symptom-Directed Therapy

Symptom-directed therapies include pulmonary rehabilitation and the use of antitussives and opioids.

Pulmonary Rehabilitation

Patients with IPF should be encouraged to enroll in pulmonary rehabilitation programs. Several small cohorts have shown that a combination of aerobic and strengthening exercises improve 6-min walk test distance and perception of dyspnea.[177–179] Furthermore, a randomized controlled study showed that a supervised exercise training program improved exercise tolerance, functional capacity, leg strength, pulmonary function, perception of dyspnea, and quality of life in patients with IPF.[180] In addition to these benefits, pulmonary rehabilitation programs provide education and psychosocial support system that also improve quality of life.

Antitussives

Therapies for cough aimed to suppress the central cough reflex (dextromethorphan), to target sensory neurons (lidocaine, benzonatate), or to act as mucolytics (beta agonists, macrolides) have limited efficacy with transient effect. However, agents such as gabapentin and amitriptyline, which target the central cough reflex, have shown to be beneficial in idiopathic chronic cough and could be useful for idiopathic pulmonary fibrosis.[181] Thalidomide, an immunomodulatory, anti-inflammatory, and antiangiogenic drug has been of interest. Thalidomide was initially used as an antiemetic during the first trimester of pregnancy, causing serious birth defects. It was later repurposed as an effective treatment of cancer-related emesis. Due to its mechanism of action, it was also studied as a potential therapy for IPF. An open-label, single-center clinical trial showed no effect in the course of IPF but significant reduction in cough.[182] A subsequent small, double-blind, placebo-controlled trial carried out in the same medical center showed that low-dose thalidomide improved cough and respiratory symptoms.[183]

Opioids

In advanced stages of the disease, many patients have severe breathlessness and anxiety. Although limited, randomized, placebo-controlled studies have investigated the effect of systemic opioids on the perception of dyspnea in patients with IPF. These studies have shown a significant difference in modified Borg score for dyspnea, exercise tolerance, anxiety, and agitation with no reduction of respiratory drive nor increase in the hospitalization rate.[184,185] Constipation and nausea are the most common side effects. Unlike systemic steroids, the use of nebulized opioids, aiming to target the opioid receptor in the respiratory tract, did not show any effect of symptom improvement. This suggests that the central mechanism for dyspnea plays a greater role in respiratory symptoms in IPF relative to local intrabronchial mechanisms.[186]

CHAPTER 55

Idiopathic Interstitial Pneumonias Other Than Idiopathic Pulmonary Fibrosis

Kelly M. Hager
Ami Rubinowitz
Mridu Gulati

INTRODUCTION

The idiopathic interstitial pneumonias (IIPs) encompass a subcategory of interstitial lung diseases (ILDs) that pose significant diagnostic and management challenges. The general diagnostic approach to these disorders is discussed elsewhere in this textbook (Chapter 52), as is the diagnosis and management of idiopathic pulmonary fibrosis (IPF) (Chapter 54). This chapter details the classification, diagnosis, and management of non-IPF forms of IIPs.

In a 2013 update, the American Thoracic Society and European Respiratory Society delineated three categories of idiopathic interstitial pneumonias: the major idiopathic interstitial pneumonias, rare idiopathic interstitial pneumonias, and a separate category for unclassifiable interstitial pneumonias. The major idiopathic interstitial pneumonias include chronic fibrosing interstitial pneumonias (idiopathic pulmonary fibrosis, idiopathic nonspecific interstitial pneumonia), smoking-related interstitial pneumonias (respiratory bronchiolitis–interstitial lung disease, desquamative interstitial pneumonia), and acute/subacute interstitial pneumonias (cryptogenic organizing pneumonia and acute interstitial pneumonia). Rare idiopathic IPs include idiopathic lymphocytic interstitial pneumonia and the newly recognized entity of idiopathic pleuroparenchymal fibroelastosis. The guidelines further demarcated a diagnostic category for unclassifiable IIP, acknowledging the clinical reality that a subset of patients may not fully meet criteria for a specific diagnosis.[1] In this chapter, after a description of the specific entities, each section ends with a discussion of current therapeutic options. This information is summarized in Table 55-1.

NONSPECIFIC INTERSTITIAL PNEUMONIA

The chronic fibrosing interstitial pneumonias include idiopathic pulmonary fibrosis, discussed in Chapter 54, and nonspecific interstitial pneumonia, which is discussed below.

Definition and Historic Perspectives

In 1994, the term *nonspecific interstitial pneumonia (NSIP)* was developed by Katzenstein and Fiorelli[2] to describe a histologic pattern that demonstrates a temporally uniform appearance of interstitial inflammation and fibrosis. This definition was further refined in 1998 when Katzenstein went on to formally designate NSIP as a distinct category within the IIPs.[3] In 2008, an American Thoracic Society report recommended that clinicians recognize idiopathic nonspecific interstitial pneumonia (iNSIP) as a distinct, rather than a provisional, clinical entity.[4] In updating the previous 2002 statement, the 2013 official classification incorporated iNSIP as a chronic fibrosing ILD within the major idiopathic IIPs.[1] The NSIP histopathologic pattern may also be seen in association with other clinical disorders, such as connective tissue diseases and hypersensitivity pneumonitis.

Underlying Disease Associations

Nonidiopathic NSIP is associated with a number of underlying causes.[5,6] NSIP is the most prevalent form of ILD to complicate connective tissue diseases (CTD) and is frequently the histologic pattern seen when ILD complicates polymyositis and dermatomyositis,[7,8] Sjögren syndrome,[9] systemic sclerosis (SSc), and interstitial pneumonia with autoimmune features (IPAF).[10,11] NSIP is seen in rheumatoid arthritis (RA), though far less commonly than usual interstitial pneumonia (UIP).[12] NSIP is also encountered in the setting of hypersensitivity pneumonitis,[13] drug reactions,[2] and some forms of familial ILD.[14] Some cases of apparently idiopathic NSIP may later develop CTD, indicating that NSIP is a forme fruste of CTD.[15]

Clinical Presentation

Idiopathic NSIP most commonly affects nonsmoking middle-aged adults between 40 and 60 years of age, with a female predilection.[2,4,16] Idiopathic NSIP is a rare disease; one retrospective series reported a prevalence of 1 to 9 per 100,000[6] while a Danish cohort study estimated an incidence of 3 per million per year.[17] Like most other IIPs, NSIP tends to present with the subacute onset of dyspnea and cough. Lung examination frequently but not universally reveals bilateral crackles. Extrapulmonary examination may provide clues to an underlying CTD (Chapter 58). For example, the presence of a heliotrope rash, shawl-like rash, and digital edema/desquamation ("mechanic's hands") suggests underlying dermatomyositis. The presence of telangiectasias, calcinosis, and sclerodactyly suggests a diagnosis of scleroderma. The presence of joint effusions and radial deviation of the MCP joints suggests an underlying diagnosis of RA. Clubbing may be seen.

Underlying causes or associated conditions may not be initially evident. A complete history regarding occupational, environmental, and medication exposures must be obtained. In addition, because NSIP is frequently associated with CTD, an exhaustive rheumatologic history should be obtained, including questions regarding the presence of arthralgias, swallowing difficulties, myopathic symptoms, rash, and mechanic's hands commonly encountered in antisynthetase syndrome, ocular and/or salivary gland dryness associated with Sjögren syndrome, and Raynaud phenomenon and swallowing difficulties characteristic of SSc.

Laboratory Testing

While most sources recommend serologic testing in the diagnosis of NSIP, there exists no standardized practice guideline in this area. The 2011 ATS/ERS/Japanese Respiratory Society/Latin American Thoracic Association guidelines recommended ANA, anticyclic citrullinated peptide, and rheumatoid factor for all patients, with more specific extractable nuclear antigen antibody and myositis antibody testing recommended depending on the clinical scenario. A small, retrospective study demonstrated the potential utility of extended autoantibody panel with 6 of 17 patients reclassified as myositis-associated ILD or IPAF after testing.[18] Repeat serologic testing should be considered, as seroconversion has been documented.[19] Hypersensitivity pneumonitis may also present as an NSIP pattern. The 2020 ATS/JRS/ALAT hypersensitivity pneumonitis practice guidelines suggested performing serum IgG testing for possible antigens.[20–23] Nonetheless, the sensitivity and specificity of such tests are highly variable and do not supplant a comprehensive exposure history.

TABLE 55-1 Key Features of Major and Rare Idiopathic Interstitial Pneumonias

	Major Idiopathic Interstitial Pneumonias					Rare Idiopathic Interstitial Pneumonias	
	Chronic Fibrosing		*Smoking Related*	*Acute/Subacute*			
	IPF	**NSIP**	**DIP/RB-ILD**	**COP**	**AIP**	**LIP**	**PPFE**
Mean age of onset	60s	50s	40s	50s	50s	50s	40s
Duration of illness	Chronic	Subacute to chronic	Subacute to chronic	Subacute	Acute	Chronic	Subacute
Frequency	47%–64%	14%–36%	10%–17%	4%–12%	Rare	Rare	Rare
Smoking	Up to 2/3	Uncommon	Most	Up to 1/2	Unknown	Unknown	Unknown
HRCT	Peripheral, subpleural; basilar predominant; reticular opacities; traction bronchiectasis architectural distortion and honeycombing	Peripheral, peribronchovascular; basal, symmetric; ground-glass opacities, reticular markings, traction bronchiectasis	DIP: peripheral or diffuse ground-glass opacities, reticular markings, ± small cysts RB-ILD: bronchial wall thickening; centrilobular ground glass nodules; patchy ground-glass opacity	Patchy, bilateral, subpleural and peribronchovascular consolidation	Diffuse consolidation and ground-glass opacities often with lobular sparing	Diffuse; ground-glass opacities; septal thickening; thin-walled cysts	Upper lobe dense subpleural consolidation with traction bronchiectasis and volume loss
Key pathologic features	Variegated temporal appearance; scant inflammation; patchy fibrosis; fibroblastic foci; honeycomb change	Uniform temporal appearance; prominent inflammation; variable, diffuse fibrosis; rare honeycomb	Uniform temporal appearance DIP: diffuse variable moderate fibrosis with diffuse intra-alveolar macrophage accumulation RB-ILD: peribronchiolar intra-alveolar macrophage accumulation with only focal, mild fibrosis	Uniform temporal appearance; moderate inflammation; intra-alveolar (Masson bodies) fibroblast proliferation; foamy macrophages	Structural cell death responses; acute inflammation; hyaline membranes may be present	Diffuse interstitial infiltration, infiltrates comprised of T and/or B cell lymphocytes, plasma cells, macrophages, lymphoid hyperplasia	Upper lobe predominant, subpleural homogenous intra-alveolar fibrosis and elastosis with marked elastin deposition around alveolar walls with preserved alveolar structure, sparse/nonspecific inflammation
Prognosis	50%–70% mortality in 5 years	<10% mortality in 5 years	DIP: 30% mortality at 10 years RBILD: Limited data but favorable prognosis compared to DIP	Rare deaths	5%0–60% mortality at 1 month	Not well defined	70% mortality in 5 years
Response to steroids	Nonresponsive	Variably responsive (particularly cellular)	Responsive	Very Responsive	Standardly given; inconsistently responsive	May be responsive	Not well defined; low dose may be effective, high dose avoided due to increased risk of infection

Pulmonary Function Testing

Pulmonary function testing demonstrates a restrictive ventilatory defect characterized by a preserved forced expiratory volume in 1 s (FEV_1)/forced vital capacity (FVC) ratio and a depressed FVC, total lung capacity (TLC), and diffusing capacity of the lung for carbon dioxide (DL_{CO}). The presence of obstructive physiology should raise suspicion of an alternate or superimposed diagnosis such as chronic obstructive pulmonary disease (COPD).

Chest Imaging

The imaging appearance of NSIP may vary depending on whether a cellular, fibrotic, or mixed form is present. Chest radiograph may be normal in patients with early disease or show nonspecific interstitial markings and ground-glass opacities mostly in the lower lobes with more advanced disease. Distribution of disease on chest computed tomography (CT) is typically peripheral and lower lobe predominant, but may also involve the upper lobes without an obvious apicobasal gradient. The disease may be patchy or peribronchovascular in distribution as well.[20–23] Subpleural sparing is often seen. The most common CT features include ground-glass density and reticular markings with or without traction bronchiectasis (Figs. 55-1 and 55-2). Honeycombing is sometimes seen in fibrotic NSIP but is usually not the dominant feature.[21,22] While the presence of classic findings on high-resolution CT (HRCT) can definitively make diagnosis of IPF in the appropriate clinical context,[24] HRCT is less accurate in establishing a diagnosis of NSIP and a surgical lung biopsy may be required.[25] NSIP may overlap with other patterns such as an organizing pneumonia pattern, although its presence modifies prognosis.[26]

Pathology

When a tissue biopsy is required for diagnosis of NSIP, video-assisted thoracoscopic surgery (VATS) is the procedure of choice because this approach yields sufficient tissue to accurately diagnose the IIPs. Bronchoscopic evaluation has limited utility. Lymphocytosis on bronchoalveolar lavage (BAL) has been reported[27] but not consistently.[28] Transbronchial biopsies and even transbronchial lung cryobiopsies typically yielding larger specimens fail to consistently establish an NSIP diagnosis when compared with surgical lung biopsy.[29]

The original description of NSIP categorizes its temporally uniform appearance of fibrosis and inflammation into three groups: those dominated by active inflammation (later called "cellular" NSIP) (Fig. 55-1), those dominated by established fibrosis (later called "fibrotic" NSIP) (Fig. 55-2), and those demonstrating a combination of inflammation and fibrosis (later called "mixed" NSIP).[1] NSIP infiltrates usually include a mixture of lymphocytes and plasma cells within the alveolar septum prominently found in the peribronchiolar interstitium. Histopathologic overlaps also may be found. Up to 79% of cases may demonstrate organizing pneumonia (OP), although OP features generally do not predominate; the finding of prominent OP suggests the presence of CTD-associated ILD.[30] Overlapping histopathologic features of hypersensitivity pneumonitis—the presence

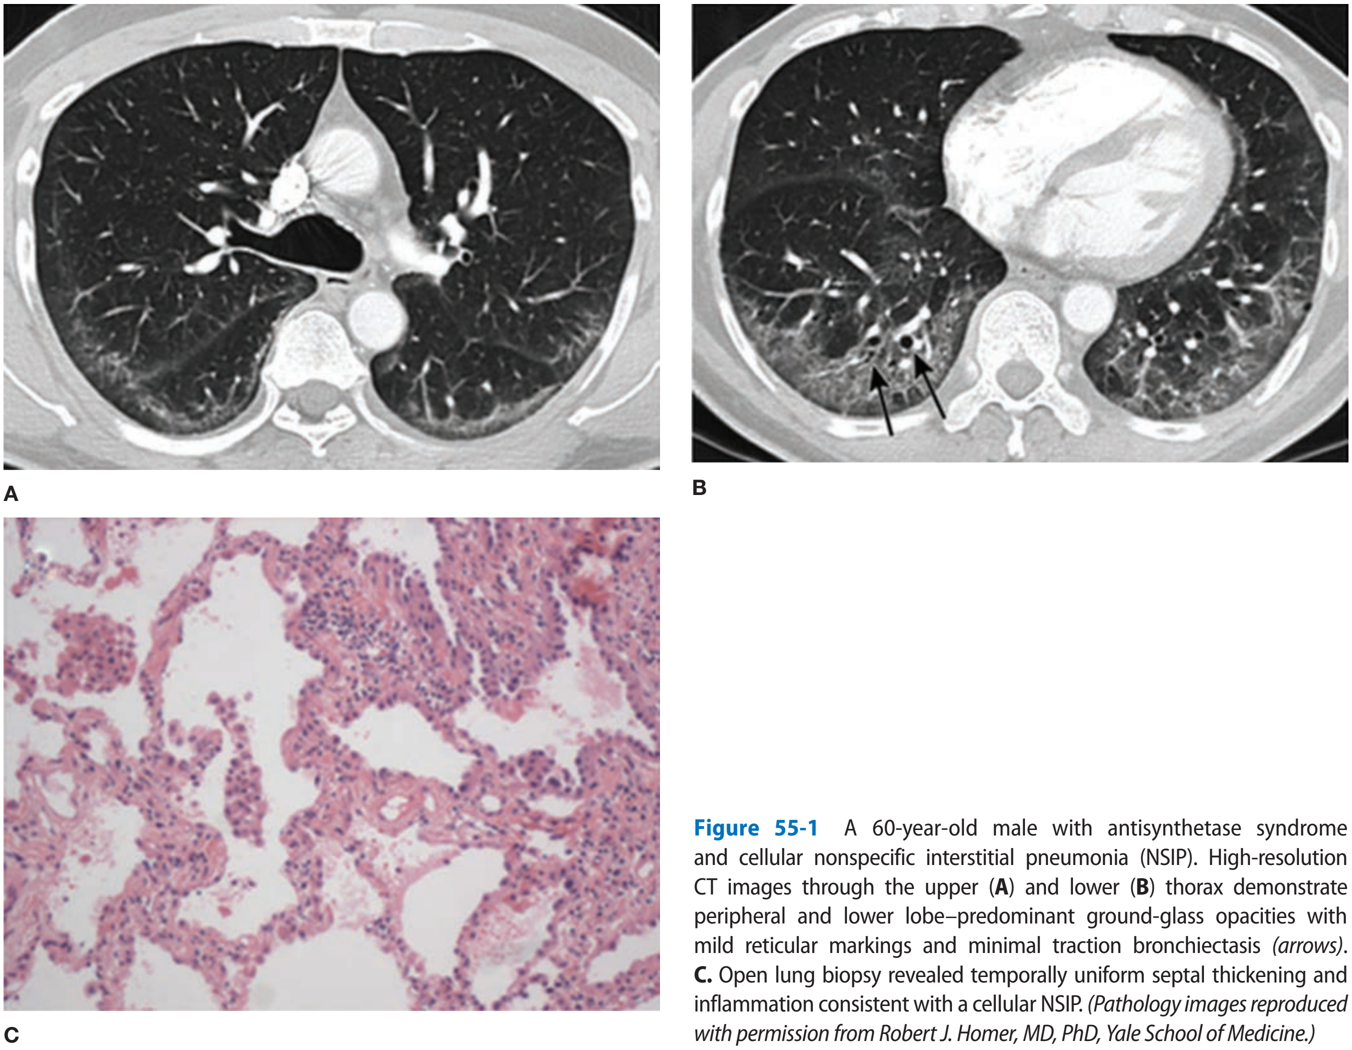

Figure 55-1 A 60-year-old male with antisynthetase syndrome and cellular nonspecific interstitial pneumonia (NSIP). High-resolution CT images through the upper (**A**) and lower (**B**) thorax demonstrate peripheral and lower lobe–predominant ground-glass opacities with mild reticular markings and minimal traction bronchiectasis *(arrows)*. **C.** Open lung biopsy revealed temporally uniform septal thickening and inflammation consistent with a cellular NSIP. *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

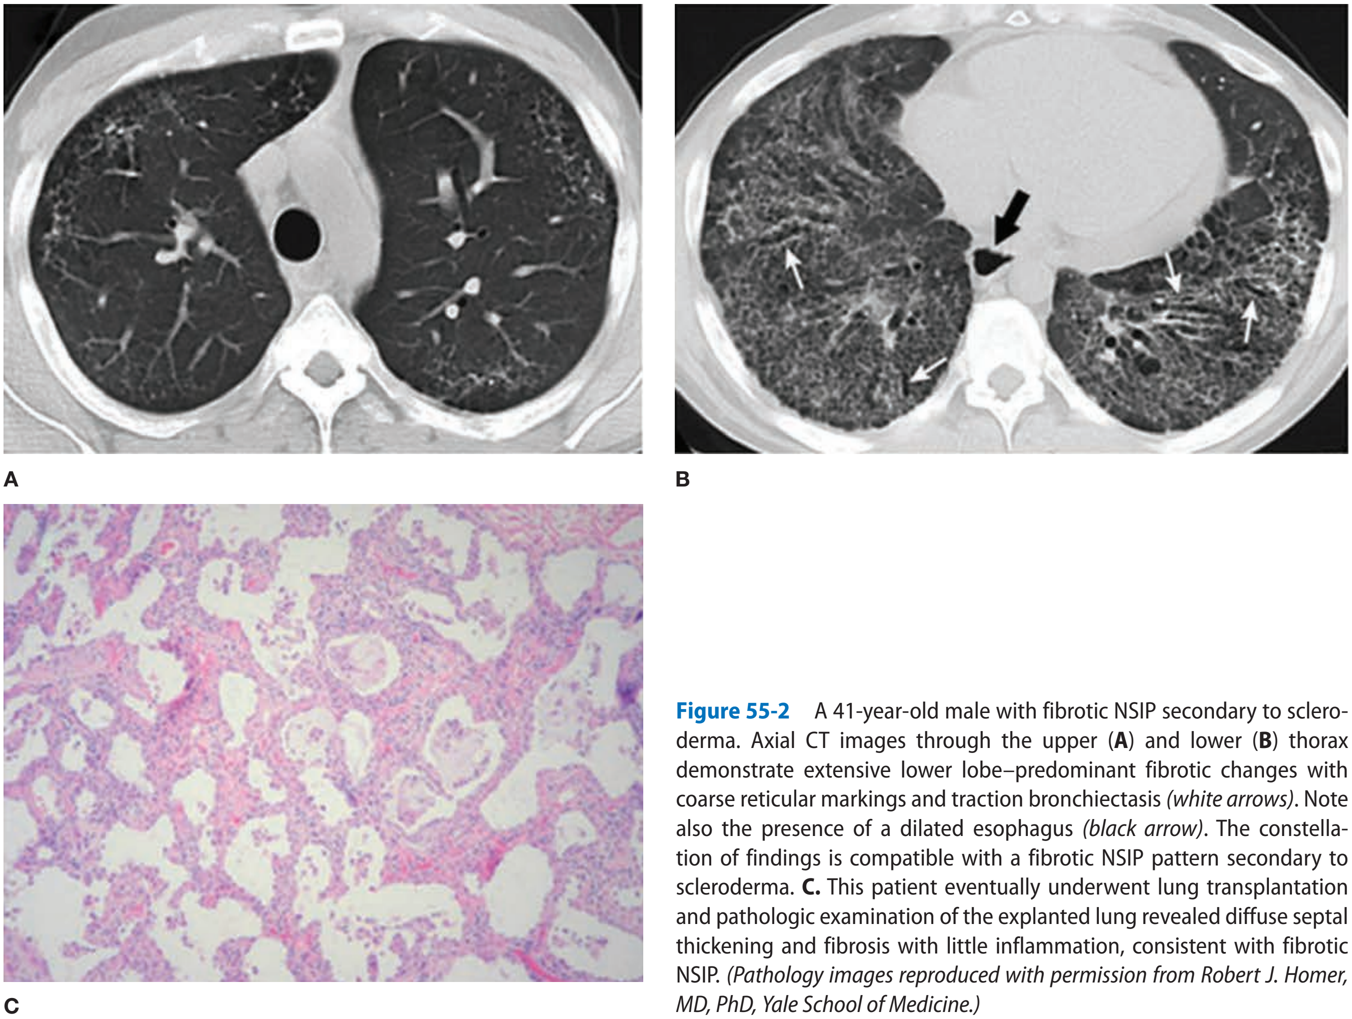

Figure 55-2 A 41-year-old male with fibrotic NSIP secondary to scleroderma. Axial CT images through the upper (**A**) and lower (**B**) thorax demonstrate extensive lower lobe–predominant fibrotic changes with coarse reticular markings and traction bronchiectasis *(white arrows)*. Note also the presence of a dilated esophagus *(black arrow)*. The constellation of findings is compatible with a fibrotic NSIP pattern secondary to scleroderma. **C.** This patient eventually underwent lung transplantation and pathologic examination of the explanted lung revealed diffuse septal thickening and fibrosis with little inflammation, consistent with fibrotic NSIP. *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

of loosely formed granulomas—may be detected and should prompt investigation for an antigen.[31] The fibroblastic foci prominently seen in UIP are not characteristic of patients with NSIP; nonetheless a small proportion of patients may demonstrate UIP and NSIP histopathologic features in different biopsy specimens, a finding that correlates with worsened prognosis.[32]

■ Clinical Course and Outcome

Early reports suggested a favorable prognosis of NSIP compared with UIP. An ATS report described 5- and 10-year survival of 80% and 73%, respectively, in iNSIP[33] while better outcomes may be associated with CTD-associated NSIP.[34] Cellular NSIP is associated with favorable event-free survival compared to the fibrotic forms.[35] Similarly, radiographic changes that would be expected to accompany fibrotic NSIP, such as honeycombing, have been associated with reduced survival, as have progressive dyspnea and desaturation during 6-minute walk tests.[33] Serial pulmonary function testing, specifically declines in FVC and $\mathrm{DL_{CO}}$, may ultimately serve as a better predictor of survival.[36] Initially reported in IPF, acute exacerbations have been reported in other fibrotic ILDs, including NSIP, and may cause rapid deterioration in previously stable patients.[37]

■ Treatment Overview

Approach and response to treatment depends on cause, severity of disease, the presence and/or the degree of fibrosis, and rate of disease progression. In very mild situations, careful observation may be initially indicated as some patients will remain stable or progress very slowly. For cases of exposure-related NSIP related to drugs or inhalation, cessation of the offending agent, particularly in the setting of mild disease, may be the sole initial treatment strategy. In patients with CTD-associated NSIP, immunosuppression may be indicated for both lung and systemic manifestations.

Regardless of treatment plan, nonpharmacologic supportive therapy should be considered. Patients with arterial hypoxemia at rest or during exercise may benefit from the administration of supplemental oxygen.[38] Patients with exercise impairment may benefit from pulmonary rehabilitation.[39] Finally, due to the rapid deterioration that is sometimes encountered in patients with NSIP, referral for orthotopic lung transplantation (OLT) should be considered for any eligible patient. The use of immunosuppression is based on the rationale that the inflammation seen on pathology contributes to disease. More recently, antifibrotics have emerged as a treatment option. Immunosuppressive and antifibrotic therapies are reviewed below.

■ Immunosuppression

The decision to embark upon a course of immunosuppression should be considered in light of the risk–benefit ratio. Similarly, when treating a patient with NSIP in the setting of CTD, the management of these medications is best performed in collaboration with the patient's rheumatologist. The data on the use of immunosuppression in NSIP have been predominantly studied in populations with concomitant CTD. Since the pulmonary and systemic involvement may demonstrate independent responses, systemic effects must also be monitored. Patients should be seen frequently so serious and potentially fatal side effects are recognized in a timely fashion. Clinicians should advise patients to remain up to date with vaccinations and avoid live vaccinations while on immunosuppression. While the risk of *Pneumocystis* pneumonia appears to be low, mortality may be quite high, with the highest risk being among patients on high-dose steroids in combination with other immunosuppressant drugs. Prophylaxis with trimethoprim/sulfamethoxazole is recommended and highly effective in preventing disease.[40]

Corticosteroids

Despite a lack of clinical trials in this area, expert opinion recommends a trial of corticosteroid therapy in patients with NSIP. Patients are typically treated with 1 mg/kg per ideal body weight of oral prednisone for several months and then assessed for evidence of objective response on PFTs or HRCT.[23] For rapidly progressive fulminant disease, pulse intravenous steroids with doses of 750 to 1000 mg per day for 3 days may be required, followed by a tapering doses. Higher response rates may be seen in patients with cellular forms of NSIP.[41] Steroid monotherapy may be insufficient to control disease, and the side effects of steroid therapy are well known and include diabetes, bone complications, cataracts, hypertension, weight gain, and opportunistic infections.[42] Hence, every attempt should be made to add a steroid-sparing agent to transition the patient completely off steroids or at least to the lowest dose possible. Bone mineral density testing should be performed to calculate fracture risk assessment for patients who are maintained on or are ready to embark upon chronic corticosteroid therapy. In addition to ensuring adequate Vitamin D and calcium supplementation, pharmacologic therapy, most often with bisphosphonates, may be indicated in patients with established osteoporosis and should be considered in patients with osteopenia.

Azathioprine

Azathioprine, an immunosuppressive agent that inhibits purine synthesis (particularly in lymphocytes), is a common alternate therapy for patients with NSIP. Azathioprine has been associated with disease stabilization in patients with NSIP and has been studied primarily in CTD-associated NSIP.[43] No large-scale clinical trials have been performed in this area. Most case series investigated azathioprine in combination with other immunosuppression including corticosteroids or as maintenance therapy after cyclophosphamide induction.[44] Because azathioprine carries several risks including bone-marrow suppression and hepatotoxicity, many centers perform genotyping for thiopurine methyltransferase prior to initiation of therapy and reduce dosing when a mutation is uncovered, although evidence for this approach is currently lacking. Of note, a randomized control trial involving azathioprine in IPF patients noted increased mortality risk,[45] and studies have indicated that a significant proportion of patients may not tolerate the drug due to non-respiratory-related side effects.[46] The total dosage is 1.5 to 2 mg/kg per day, with a maximum dosage of 200 mg/day.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is an immunosuppressive drug that inhibits B and T cell function through inhibition of purine synthesis. It has been particularly studied in CTD-associated interstitial lung disease. In the Scleroderma Lung Study II, patients were randomized to oral MMF for 24 months versus 12 months of cyclophosphamide followed by 12 months of placebo. Improvements in FVC were noted at 24 months with fewer side effects in the MMF arm. Other studies demonstrated a role for MMF in patients with other forms of CTD-ILD[47] and IPAF.[48] In addition to increasing risk of infection, common side effects of MMF include diarrhea and nausea. Prolonged usage has been associated with some cancers and lymphoma.

Cyclophosphamide

Cyclophosphamide is used in patients with significant or rapidly progressive lung involvement. In a prospective study comparing patients with confirmed fibrotic NSIP versus those with UIP/IPF receiving pulse therapy with methylprednisolone followed by low-dose prednisone and cyclophosphamide, 33% of subjects with NSIP, compared with 15% of UIP subjects, improved with steroids alone and 66% improved with combined therapy.[49] Perhaps the best evidence for a therapeutic benefit of cyclophosphamide was seen in patients with SSc-ILD (most of whom have NSIP) randomized to placebo or cyclophosphamide. A small but significant improvement in lung function was noted in subjects assigned to the treatment arm,[23] though subsequent analysis found this effect to dissipate after 2 years.[50] Because cyclophosphamide is associated with many side effects including bone-marrow suppression, hemorrhagic cystitis, and the long-term risk of bladder cancer and hematologic malignancies, it is reserved for severe and progressive cases of NSIP and should only be used by experienced practitioners with appropriate monitoring. As previously mentioned, the Scleroderma Lung Study II noted that patients on MMF had an equivalent response compared with those on cyclophosphamide but experienced fewer adverse effects; as such, clinicians have increasingly steered patients towards MMF. The target dose of MMF is 1500 mg orally twice daily; however, many are unable tolerate the full dose. Enteric-coated mycophenolate sodium may be substituted for those with intolerable gastrointestinal side effects.

Rituximab

Rituximab, an anti-CD20 B cell–depleting monoclonal antibody, has demonstrated potential utility in a number of studies involving connective tissue diseases including dermatomyositis-polymyositis, scleroderma, and RA.[51–53] A recent systematic review and meta-analysis of two randomized control trials and several prospective and retrospective studies in scleroderma patients demonstrated improvement in FVC of 7% at 12 months.[52] Several additional case series and retrospective studies have demonstrated responses in polymyositis patients; one study of 24 patients reported of improvements in FVC and D_{LCO} of 24% and 17% respectively, and a reduction of 34% in radiographic ILD extent, with greater improvements reported amongst those with disease duration less than 12 months or those with acute exacerbations.[54] Rituximab dosing remains variable, but 1 g given intravenously spaced 2 weeks apart with repeat dosing at 6 months has been reported. Rituximab has been associated with prolonged immunosuppression. Infusion reactions including drops in blood pressure, mild throat tightening, sweating, numbness, and nausea can occur; premedication with antihistamines and acetaminophen may reduce reactions. Panhypogammaglobulinemia resulting in infections can occur, and intravenous immunoglobulin should be considered in such patients.

Other Immunosuppressive Agents

A role for tacrolimus in the treatment of NSIP is supported by a case series of patients with polymyositis and dermatomyositis-related ILD. In one case series of 49 previously untreated patients, the addition of tacrolimus to conventional therapy with corticosteroids and intravenous cyclophosphamide or cyclosporine led to improved disease-free survival in myositis-associated ILD.[55] However, because no large-scale studies have been performed, consideration of this agent for the treatment of NSIP should be on a case-by-case basis by physicians who are experienced in the interpretation of serum levels. The most feared side effect is renal toxicity, which can be permanent and lead to kidney failure. Other adverse effects, including neurotoxicity and metabolic derangements, have been reported.

Tocilizumab is a humanized, anti–interleukin 6 receptor antibody approved by the FDA for slowing lung function decline and may be considered as an alternative to MMF. A phase 3 clinical trial (fassCinate)[56] demonstrated that fewer subjects experienced lung function decline in the open-label extension. Another study showed a reduction in FVC decline at 48 weeks in patients treated with tocilizumab compared with placebo.[57] A multicenter retrospective study of RA-ILD patients, including 13 patients with NSIP patterns, suggested potential disease stability and even in improvement in 1 case.[58] Of note, 6 cases of acute exacerbations of underlying ILD have also been reported in RA-ILD patients on tocilizumab therapy.[57,59]

■ Antifibrotics

The antifibrotic therapies nintedanib[60] and pirfenidone[61] were first approved in the United States in 2014 for IPF after the results of large, multicenter, international, randomized, controlled trials demonstrated slowing of disease progression. Subsequent studies investigated the role of antifibrotic therapies in other fibrotic interstitial lung diseases including NSIP. Pirfenidone is a pyridine compound whose mechanism remains to be fully elucidated but has antifibrotic as well as antioxidant and anti-inflammatory properties. A multicenter, double-blind, randomized, placebo-controlled international study of pirfenidone patients with progressive fibrotic ILD (presumably including NSIP patients) failed to meet the prespecified primary endpoint of mean predicted change in FVC from baseline by home-based spirometry, but did demonstrate disease slowing in secondary endpoints including FVC and $\mathrm{DL_{CO}}$ decline in pulmonary function testing at the clinical site and a reduced decline in 6-minute walk distance.[62]

Two recent multicenter studies confirmed the efficacy of nintedanib, a multiple-receptor tyrosine kinase inhibitor with antifibrotic properties, in fibrotic interstitial lung diseases beyond IPF. Common side effects include diarrhea, while other side effects include hepatotoxicity, increased risk of cardiovascular disease, GI perforation, and potential increased risk of bleeding. In the INBUILD trial,[63] reduced declines in FVC were seen across all subgroups of non-UIP patients including those with iNSIP.[64] The SENSCIS trial[65] established a role for nintedanib in patients with scleroderma-associated lung disease, demonstrating reduced declines in FVC at 52 weeks; the radiographic description of these patients included findings of ground-glass opacities suggesting the presence of NSIP. In light of these recent trials, nintedanib has been FDA approved for use in fibrotic ILDs outside of IPF.

SMOKING-RELATED INTERSTITIAL PNEUMONIAS: RESPIRATORY BRONCHIOLITIS–ASSOCIATED INTERSTITIAL LUNG DISEASE AND DESQUAMATIVE INTERSTITIAL PNEUMONIA

The entities of respiratory bronchiolitis–associated interstitial lung disease (RB-ILD) and desquamative interstitial pneumonia (DIP) are part of a spectrum of disorders affecting smokers. Important clinical and pathologic considerations in these two entities are described below.

■ Definition and Historic Perspectives

While clinically regarded as two discrete forms of IIPs, RB-ILD and DIP are generally thought of as representing ends of a continuous spectrum of disease primarily affecting tobacco smokers. The diagnostic distinction persists due to evidence indicating that RB-ILD and DIP have divergent natural histories and prognoses. The pathologic hallmark of both diseases feature cytoplasmic accumulation of golden-brown pigment in macrophages. RB-ILD pathology appears to reflect inhalational exposure, as findings center around the bronchioles with peribronchiolar inflammation and fibrosis. In contrast, DIP involves the airways but also extends into the alveolar space and may even include mild to moderate associated interstitial fibrosis. Because RB-ILD and DIP reactions are frequent and often incidental findings in the lung tissue of smokers, formal clinical diagnosis of RB-ILD or DIP hinges upon the presence of symptomatic, radiographic, and functional impairment. Taken together, RB-ILD and DIP account for up to 15% to 20% of patients with biopsied IIPs.[66–69]

■ Clinical Presentation

Patients diagnosed with RB-ILD and DIP are typically males in the fourth or fifth decade of life with an average 30-pack-year smoking history. Affected patients report nonspecific complaints of progressive dyspnea and nonproductive cough. Physical examination may be normal but might reveal dry inspiratory crackles and clubbing as seen in other forms of ILDs. Extrapulmonary findings are usually absent.

■ Underlying Associations

Tobacco smoke exposure accounts for most cases of RB-ILD and DIP, despite their categorization as “IIPs.” In fact, it has been reported that up to 90% of RB-ILD and DIP cases are causatively linked to tobacco smoke.[66] However, in one review of 49 cases, only 60% of DIP patients versus 93% of RB-ILD patients had a prior smoking history.[70] Although the lower prevalence of smoking in this study compared to prior studies may reflect referral bias, investigators should remain cognizant that such pathologies can occur independently of smoking. When viewed in this light, it is relevant that a number of additional exposures have been reported in association with DIP such as marijuana smoking, diesel fumes, beryllium, copper, fire extinguisher powder, asbestos, and certain chemicals used to process textiles.[70–73] DIP has also been reported as a complication of autoimmune disorders including RA and scleroderma[71,74–76] and has occurred in association with infections such as hepatitis C, cytomegalovirus, and *Aspergillus*.[77–79] Idiopathic DIP also has been reported.[70] RB-ILD established by surgical lung biopsy has been reported in association with an electronic nicotine delivery system.[80]

Genetic factors seem unlikely to play a dominant role; however, a few studies, particularly among children and siblings, have implicated genetic abnormalities of surfactant function, such as mutations in SP-B, SP-C, and ABCA-3 genes.[81–83] The applicability of these studies to the adult IIPs described herein remain uncertain. The difficulty in determining the contribution of other possible exposures may occur because when evaluating individuals with a smoking history, clinical providers dismiss the possible contribution of alternate etiologies.

DIP is often radiographically indistinguishable from NSIP.[84,85] Since many individuals with conditions such as rheumatologic disease do not proceed to lung biopsy, the specific underlying pathology of the associated IIP may remain unconfirmed and individuals may be assumed to have NSIP. DIP may co-exist with other pathologies including NSIP or other smoking-associated interstitial lung disease entities such as emphysema or pulmonary Langerhans cell histiocytosis.[86,87] The clinical significance of the radiographic and pathologic changes related to RB-ILD or DIP will vary particularly by extent of such findings.

■ Pulmonary Function Testing

Patients with RB-ILD often manifest a restrictive physiologic pattern with concomitant reduction in $\mathrm{DL_{CO}}$. However, given the bronchiolocentric nature of the pathology, a mixed pattern with some elements of obstruction also may be seen. DIP patients generally demonstrate restrictive ventilatory defects along with reduction in diffusion capacity. Hypoxemia may be seen in more severely affected patients. On occasion, spirometry and lung volume impairments seem less severe compared with the patient's clinical status. This phenomenon may be due to the mixed or obstructive patterns caused by the airway-centered nature of RB-ILD or concomitant smoking-related lung pathologies such as COPD.

■ Chest Imaging

The imaging findings of RB-ILD are usually subtle and not visualized on chest radiograph. CT findings include subtle, mild, diffuse or upper lobe-predominant centrilobular ground-glass nodules, and patchy ground-glass densities (Fig. 55-3).[20,23,88,89] Ancillary findings associated with cigarette smoking, including bronchial wall thickening from chronic bronchitis and tissue rarefaction and bullae reflecting emphysema, also may be present. Radiographic features of respiratory bronchiolitis with fibrosis (RBF) should not be confused with the specific ILD entity of RB-ILD. RBF is a localized area of interstitial fibrosis typically characterized by a circumscribed area of upper- and mid-zone subpleural foci of emphysema and reticulation.[90] These lesions may regress with smoking cessation.[91] The main alternative diagnosis in a patient with centrilobular ground-glass nodules on CT is subacute hypersensitivity pneumonitis. However, the ground-glass nodules with hypersensitivity pneumonitis are usually not as subtle as those seen with RB-ILD.

Similar to RB-ILD, the chest radiograph features in DIP are usually quite faint, although sometimes hazy, nonspecific, ground-glass opacities may be present. Peripherally located ground-glass opacities (Fig. 55-4) are the most common finding on CT, but they can also be diffuse.[75,79,81,92] Other CT findings including reticular markings and small cysts (which may indicate a component of fibrosis)[75,79,81,92] can be seen, but more extensive fibrotic changes such as traction bronchiectasis and honeycombing are rare. Bronchial wall thickening and emphysema may be seen as well.[75,79,81] When peripheral ground-glass opacities exist in this disease, the differential diagnosis includes NSIP, OP, and chronic eosinophilic pneumonia.

■ Pathology

The diagnosis of RB-ILD and DIP hinges upon a comprehensive clinical assessment integrating history, physical examination, PFTs, and HRCT. RB-ILD and DIP should be distinguished from respiratory bronchiolitis (RB) and respiratory bronchiolitis with fibrosis (RBF). Respiratory bronchiolitis, also referred to as smoker's bronchiolitis, was first described by Niewoher in 1974 and describes an inflammatory reaction of the small airways associated with an increase in pigmented macrophages occurring in response to tobacco smoke. Respiratory bronchiolitis with fibrosis (RBF), also referred to as airspace enlargement with fibrosis or smoking-related interstitial fibrosis in the literature, is a localized interstitial fibrosis

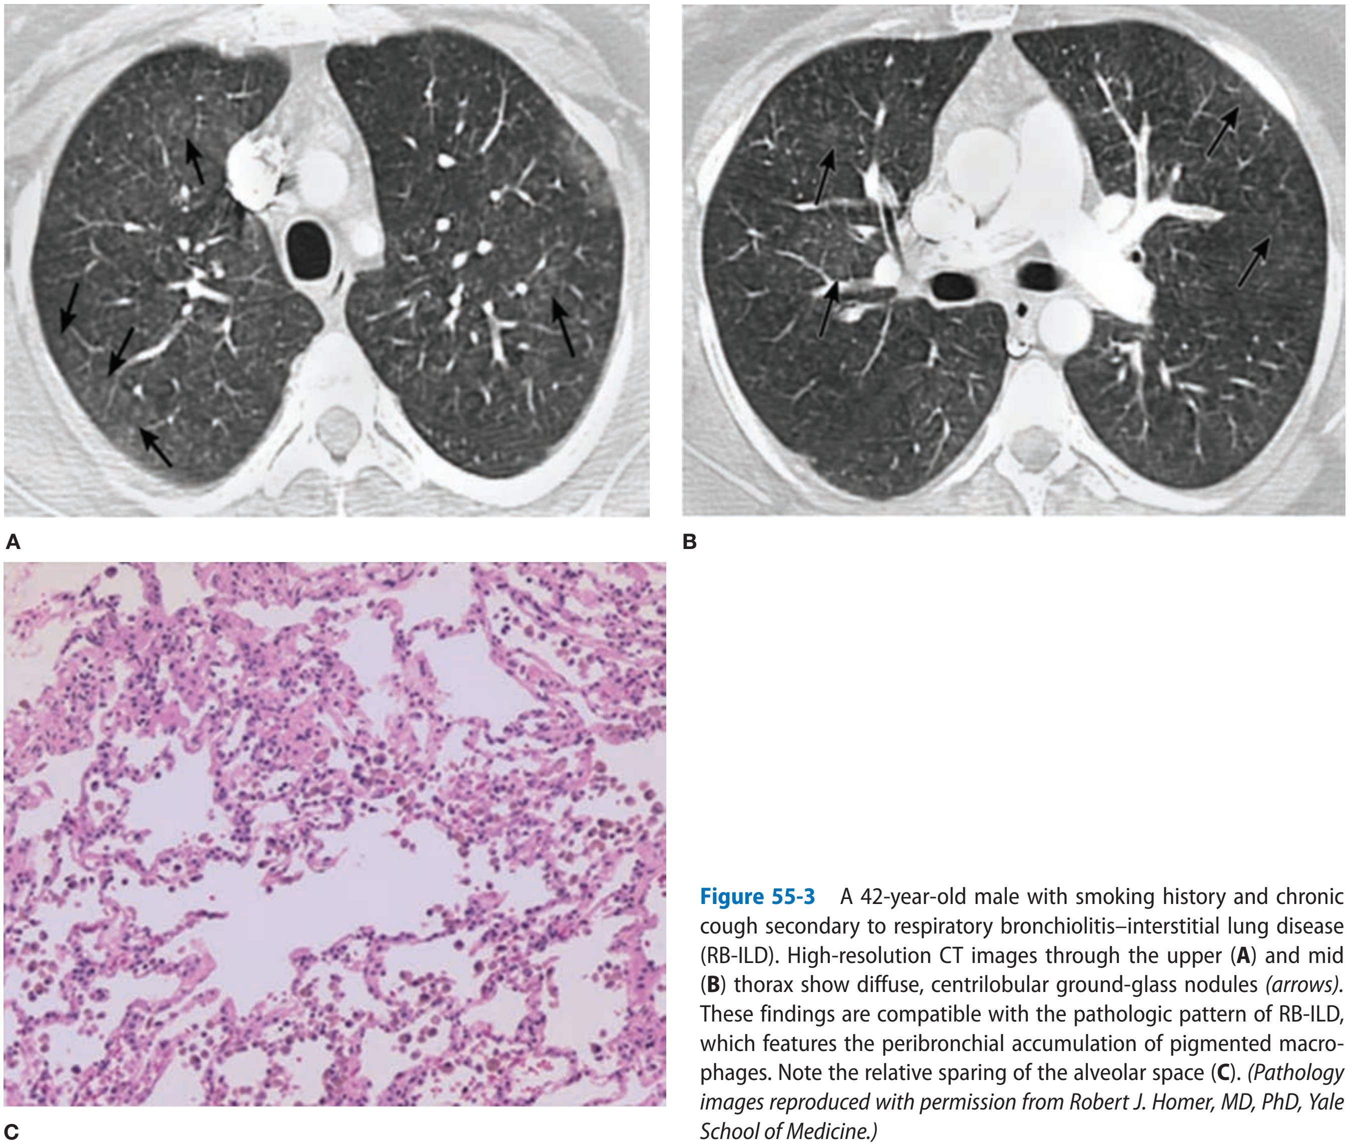

Figure 55-3 A 42-year-old male with smoking history and chronic cough secondary to respiratory bronchiolitis–interstitial lung disease (RB-ILD). High-resolution CT images through the upper (**A**) and mid (**B**) thorax show diffuse, centrilobular ground-glass nodules *(arrows)*. These findings are compatible with the pathologic pattern of RB-ILD, which features the peribronchial accumulation of pigmented macrophages. Note the relative sparing of the alveolar space (**C**). *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

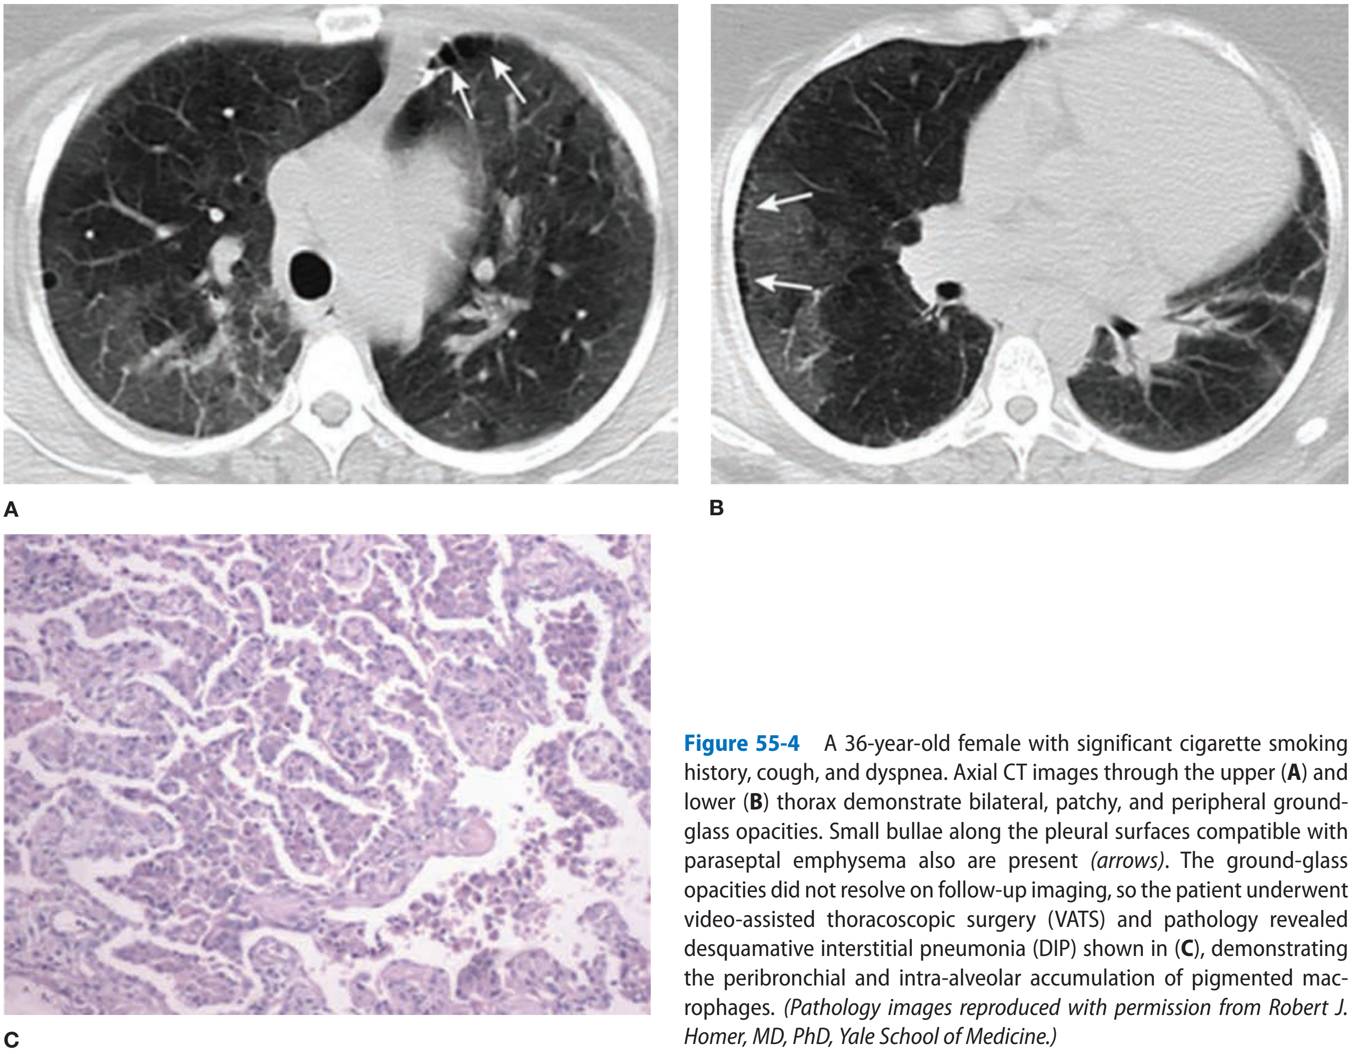

Figure 55-4 A 36-year-old female with significant cigarette smoking history, cough, and dyspnea. Axial CT images through the upper (**A**) and lower (**B**) thorax demonstrate bilateral, patchy, and peripheral ground-glass opacities. Small bullae along the pleural surfaces compatible with paraseptal emphysema also are present *(arrows)*. The ground-glass opacities did not resolve on follow-up imaging, so the patient underwent video-assisted thoracoscopic surgery (VATS) and pathology revealed desquamative interstitial pneumonia (DIP) shown in (**C**), demonstrating the peribronchial and intra-alveolar accumulation of pigmented macrophages. *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

associated with cigarette smoking. Pathologically, the lesion is characterized by a circumscribed area of hyaline paucicellular interstitial fibrosis and emphysema, emanating from the respiratory bronchiole and reaching the pleura.[90] In contrast to the above entities, RB-ILD and DIP are clinically significant forms of ILD.

Because the histopathology of DIP and RB-ILD may exist in the lung tissue of asymptomatic smokers, pathology alone is not diagnostic. Bronchoscopy may have a role in ruling out other processes resembling RB-ILD or DIP. BAL reveals characteristic pigmented macrophages. A pronounced eosinophilia has also been reported in BAL specimens of some DIP patients. Investigators have suggested that in the appropriate clinical setting and BAL profile, transbronchial biopsy showing RB may be sufficient to support the diagnosis of RB-ILD. The role of transbronchial lung cryobiopsies yielding larger specimen sizes than traditional transbronchial biopsies will likely continue to expand.[93]

Nonetheless, for both RB-ILD and DIP, surgical lung biopsy may be necessary to formally establish the diagnosis as well as to exclude alternative causes. The pathologic hallmark of RB-ILD and DIP centers around the accumulation of pigmented macrophages, commonly referred to as smoker's macrophages. These macrophages contain iron and display glassy eosinophilic cytoplasm with a finely granular, yellowish-brown pigment that likely contains components of tobacco smoke. In heavy smokers, the pigmentation may become coarser, making the distinction from hemosiderin deposition seen in chronic alveolar hemorrhage more challenging.[70,94] In the 1980s, Myers described the phenomena of RB-ILD characterized by the intensified RB response.[95] Lung tissue from RB-ILD may demonstrate a chronic inflammatory cell infiltrate as well as a peribronchiolar fibrotic pattern more pronounced than that of uncomplicated RB (Figs. 55-3 and 55-4).

First described by Liebow in 1965,[96] DIP was highlighted as a diagnostic entity in a 1978 study by Carrington.[97] Comparison of DIP and RB-ILD reveals that in DIP the macrophages extend more diffusely into the lobule in contrast to the more limited peribronchiolar involvement found in RB-ILD, and that interstitial fibrosis, giant cells, and eosinophils are more commonly found in DIP (Fig. 55-4). Pathologists must exclude the presence of alternative ILDs on biopsy. A clinical diagnosis of RB-ILD or DIP necessitates overall assessment of the patient incorporating pathologic and radiographic findings, functional impairment, and exclusion of other diagnostic considerations pathologically and radiographically.

■ Clinical Course, Outcomes, and Treatment

Patients with RB-ILD or DIP generally have less fibrosis and experience a more favorable prognosis compared with IPF, perhaps in part due to the finding that smoking cessation and corticosteroids are often effective therapies in RB-ILD and DIP patients.[68,69,98] Progressive disease is uncommon in RB-ILD and is more often seen in patients with DIP, as one study found that 33% of DIP patients versus 64% of RB-ILD patients experienced objective radiographic or physiologic improvement.[66] Similarly, another study found that 26% of patients with DIP died compared to no patients with

RB-ILD, a finding that confirmed prior work by Carrington and Yousem.[94,97,99]

■ Smoking Cessation

The cornerstone of treatment for these diseases is tobacco smoking cessation. In patients with mild to moderate symptoms and impairment, a period of observation after smoking cessation is reasonable. Many patients stabilize and improve. Concomitant corticosteroid therapy often confounds interpretation of the efficacy of smoking cessation alone,[68] and earlier studies failed to comprehensively characterize the effect of smoking cessation. Additional confounders that complicate the assessment of improvement include the presence of other smoking-related lung pathologies such as emphysema, whose contribution to impairment will not generally respond to any intervention.

■ Corticosteroids and Immunosuppression

When symptoms and impairment are severe, treatment with systemic corticosteroids may be of benefit. A 6- to 9-month course of therapy with prednisone starting at a dose of 40 to 60 mg per day for 6 weeks is reasonable. The role of alternative immunosuppressants used in other ILDs is less defined in RB-ILD and DIP, but their use has been reported.[100] Macrolide antibiotic therapy has been reported to be an effective steroid-sparing treatment in DIP.[101] Lung transplantation may be necessary for patients with severe progressive disease. Recurrence of disease after transplant has been reported.[90]

ACUTE/SUBACUTE INTERSTITIAL PNEUMONIA: CRYPTOGENIC ORGANIZING PNEUMONIA

The entity of cryptogenic organizing pneumonia was described more than 30 years ago. Important clinical aspects and associations are described below.

■ Definition and Historic Perspectives

First described by Davison[102] and Epler[103] in the early 1980s, cryptogenic organizing pneumonia (COP) was categorized as an IIP in the 2002 working group sponsored by the ATS and the European Respiratory Society (ERS).[23] The pathologic hallmark of COP consists of whorls of myofibroblasts and inflammatory cells in a connective tissue matrix within the distal airspaces. This nonspecific pathologic pattern is termed *organizing pneumonia (OP)* and is found in a variety of settings including infection, drug toxicity, posttransplant, radiation exposure, and rheumatologic conditions; it is only in the absence of an associated condition or inciting factor that clinicians may establish a diagnosis of COP. Therefore, the diagnosis of COP rests on an integrated assessment of clinical symptoms, radiographic patterns, compatible histopathologic features (when available), and the exclusion of other associated causes and conditions.

The pathology was initially called *bronchiolitis obliterans organizing pneumonia (BOOP)*, a term that initially dominated the North American literature and was included in the seminal paper by Katzenstein and Myers in 1998.[104] Given clinical confusion between the term BOOP and the distinct airway-centered disease of bronchiolitis obliterans syndrome ("BOS"), the terminology was changed in 2002. However, because many cases of COP are associated with an underlying etiology, the inclusion of COP as an "idiopathic" interstitial pneumonia has led to confusion for some. Perhaps most perplexing to clinicians is the fact that the disease in COP dominates the airspaces and not the interstitium. However, the working group justified the inclusion of COP within the IIPs because in clinical practice COP is part of the differential diagnosis of other IIPs, and because interstitial inflammation and fibrosis may be present in COP. A unique variant of COP, known as the cicatricial form (CCOP) in which the loose fibromyxoid connective tissue progresses to dense collagenized scar tissue with preservation of underlying lung architecture, also has been described in the literature.[105]

■ Clinical Presentation

Similar to other IIPs, the epidemiology of COP is not well characterized, although it seems to affect both genders equally with a mean age of onset of 58 years. Nonsmokers or former smokers may be affected more frequently than current smokers.[106] The classic presentation of COP includes an initial prodromal flu-like illness with symptoms of fever, cough, and dyspnea. Hemoptysis, chest pain, arthralgias, or myalgias are uncommon. Chest auscultation may be clear or may reveal crackles. Patients are frequently treated with multiple courses of antibiotics before being diagnosed. The presence of systemic symptoms and/or findings consistent with CTD should lead to careful investigation for an associated underlying disease.[107]

Differential diagnostic considerations include hypersensitivity pneumonitis, chronic eosinophilic pneumonia, pulmonary lymphoma, and diffuse alveolar damage more commonly seen in acute respiratory distress syndrome. Acute fibrinous organizing pneumonia (AFOP) is included in the clinical spectrum of organizing pneumonia and is characterized by intra-alveolar fibrin depositions, referred to as fibrin "balls," associated with organizing pneumonia but without hyaline membranes. Like OP, AFOP can be idiopathic or can occur in association with CTD, hypersensitivity pneumonitis, infection, and/or drug toxicity.[108] Granulomatous organizing pneumonia (GOP) also has been described as a possible variant of OP; histopathologic features of GOP include OP in association with small poorly formed nonnecrotizing granulomas.[108,109]

■ Underlying Associations

A diagnosis of *COP* requires exclusion of associated causes. Many viral, bacterial, fungal, and parasitic infections have been implicated,[106,110] as has influenza A H1N1.[111] OP is a frequently encountered manifestation of drug-induced lung disease caused by antibiotics such as nitrofurantoin; medications such as phenytoin, amiodarone, sulfasalazine;[112] and illicit drugs such as cocaine.[113] Occupational exposures are also associated with an OP pattern of lung injury including but not limited to the aerosolized textile dye Acramin FWN, titanium nanoparticles in paint, and certain chemicals used in spice processing.[114–116] OP has been reported in patients with dermatomyositis-polymyositis,[8,117–121] RA,[122–124] scleroderma,[74,75,125] and systemic lupus erythematosus.[126–128] Because this form of lung injury may present as the initial manifestation of systemic disease, rheumatologic serologies can be helpful in identifying the presence of coexisting CTD. OP may be present in other inflammatory diseases such as Crohn disease and ulcerative colitis.[129] Radiotherapy treatment is also associated with the development of OP, particularly 3 to 6 months following treatment for breast cancer. Compared to radiation pneumonitis, which is fairly well circumscribed and characterized by retracted lung and traction bronchiectasis, postradiotherapy OP occurs diffusely, is migratory, and is highly steroid responsive.[130]

While BOS is the most commonly reported lung injury pattern in patients experiencing lung transplant rejection, OP patterns also have been described.[131,132] Similarly, bone-marrow transplant recipients may develop OP as a manifestation of transplant rejection, graft-versus-host disease, or idiopathic pneumonia syndrome.[133–135] OP can also complicate malignant or hematologic conditions such as various forms of acute and chronic leukemias and lymphomas.[136] It has also been suggested that gastroesophageal reflux with silent aspiration may play a role in the development of OP; however, this association has not been firmly established.[137] A recent study did find an association between more frequent relapse and severe disease in patients with co-existing GERD, warranting further investigation.[138]

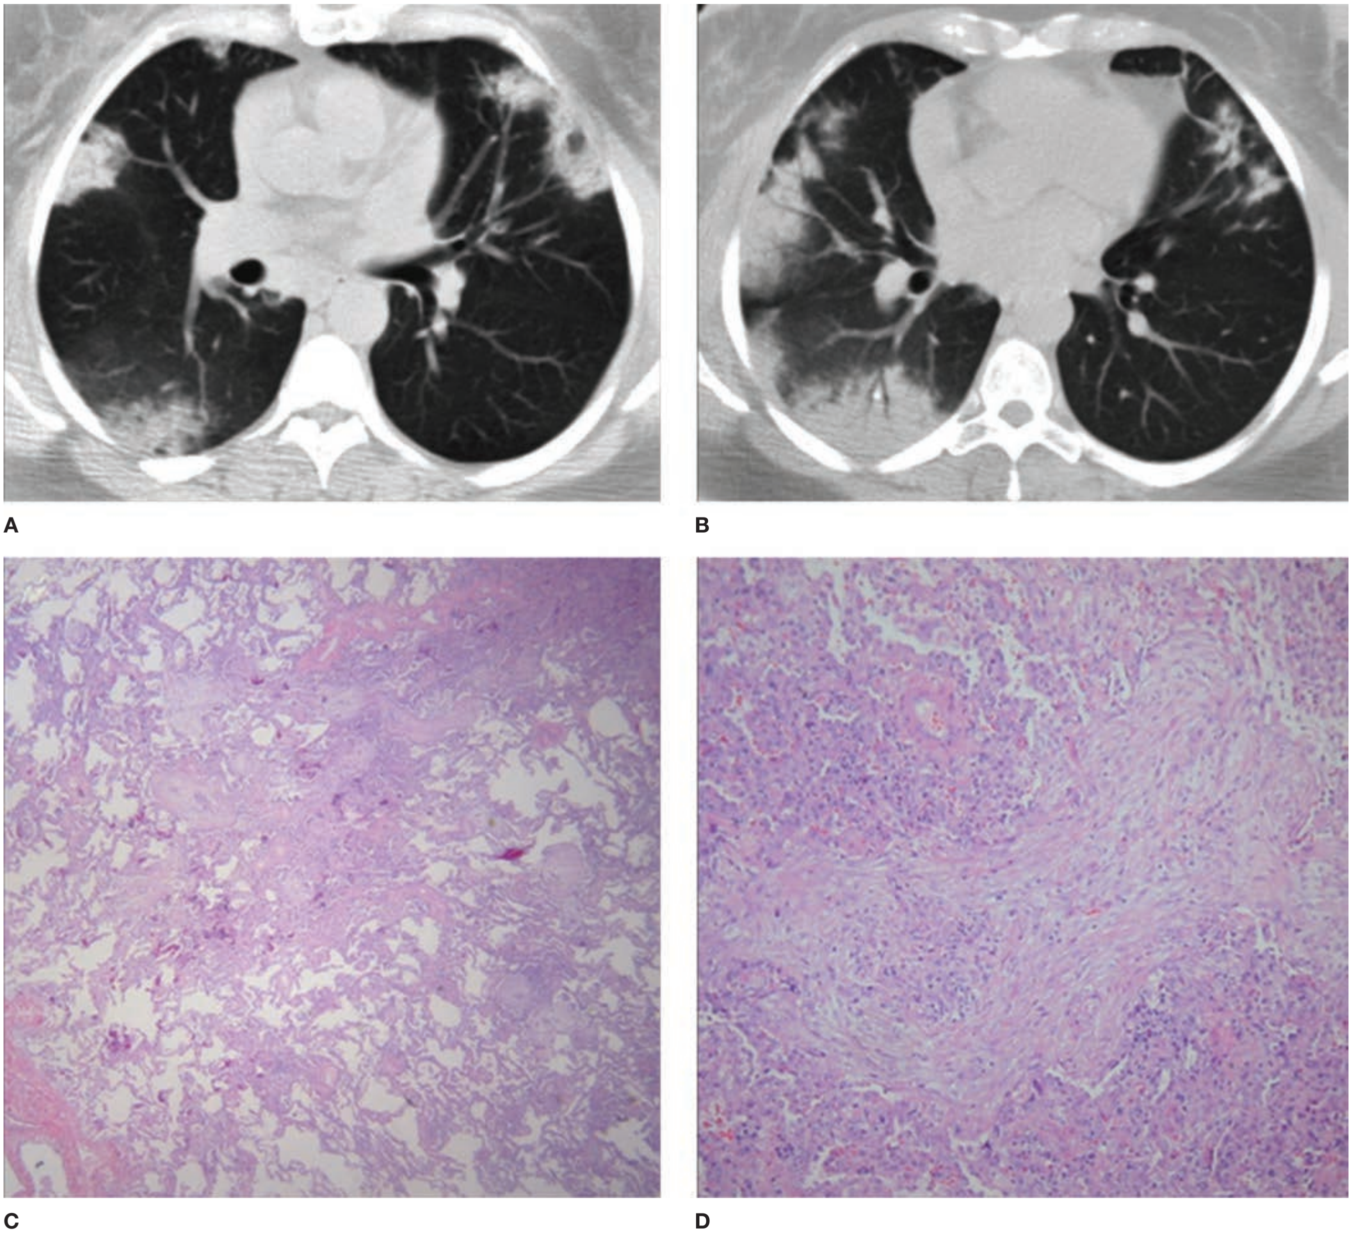

Figure 55-5 A 50-year-old female with cough and dyspnea secondary to organizing pneumonia (OP). Axial CT images through the mid (**A**) and mid to lower (**B**) thorax demonstrate multifocal, peripheral areas of consolidation with a distribution compatible with OP. Low- and high-power views (**C, D**) of lung tissue from this patient reveal a patchy organizing pneumonia pattern of exudates, fibroblasts, and inflammatory cells. *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

■ Pulmonary Function Testing

As in other IIPs, a restrictive ventilatory defect characterized by a reduction in TLC is generally present. In a subset of patients, an obstructive ventilatory defect can be found. Hypoxemia is typically mild, although in a subgroup of patients with infiltrative opacities, severe hypoxemia may be seen.[139,140]

■ Chest Imaging

OP displays a variable imaging appearance. The chest radiograph usually shows nonspecific patchy areas of consolidation. Sometimes the imaging appearance mimics infectious pneumonia with lobar consolidation that is unresponsive to antibiotics. Peripheral, patchy, and peribronchovascular areas of ground-glass opacity and consolidation are the most classic CT findings (Fig. 55-5).[20,23,141,142,143] Nodular areas of ground glass and consolidation as well as fleeting or migratory areas of consolidation also can be seen with OP.[20,23,141,142,143] Findings suggestive of fibrosis, such as reticulation, architectural distortion, traction bronchiectasis, and honeycombing, are not typically present with this entity. An area of ground-glass opacity surrounded by a rim of increased density, also known as the atoll (or reverse-halo) sign, when present, is strongly suggestive of OP[141,142] but can also be present with other entities such as vasculitis, certain infections, or pulmonary infarction. Presentation as a solitary mass has been reported, although this is rare.[144,145]

■ Pathology

When the clinical presentation and chest imaging is insufficient for a confident diagnosis of COP, bronchoscopy with transbronchial biopsy or surgical lung biopsy can be employed. BAL typically reveals significant accumulation of lymphocytes, neutrophils, and eosinophils. Transbronchial biopsies may be performed to make a diagnosis; however, the quantity of lung tissue obtained during these procedures is quite small and may be insufficient to fully evaluate the spectrum of pathology that may exist within the lung parenchyma.[146–148] Thus, larger lung tissue specimens obtained by VATS are frequently used to provide the opportunity for more thorough analyses. The pathology of OP is characterized by intraluminal plugs of inflammatory debris within the alveolar ducts and surrounding alveoli. The plugs consist of buds of granulation tissue, along with whorls of fibroblasts and myofibroblasts in a connective tissue matrix referred to as Masson bodies (Fig. 55-5). OP patterns can be seen concomitantly in patients with NSIP or UIP, and may in certain patients represent an exacerbation of underlying ILD. In this setting, interpretation of the pathology in the context of the radiographic and clinical features can greatly aid in accurate diagnosis.

■ Clinical Course and Outcome

Patients with mild or asymptomatic disease may not require treatment.[149] When compared with other fibrotic lung diseases, COP is impressively steroid responsive—although a significant proportion of patients, ranging from 13% to 58%, experience relapse. Radiographic evidence of disease in all three lung zones, pathologic evidence of high levels of intra-alveolar fibrin on lung biopsy, and high neutrophil percentage on BAL[150] are associated with increased risk of relapse.[151] Studies investigating predictors of relapse have identified associations between radiographic findings of traction bronchiectasis and bilateral shadow patterns, FVC and Pa_{O_2}/Fi_{O_2} at presentation, and protein level at presentation, but larger-scale studies are still needed.[152,153] Fortunately, relapses are not associated with poorer long-term outcomes and death is very infrequent.

■ Pharmacologic Therapy

Historically, a 6-month course of treatment has been advised. More recently, shorter 3-month durations of corticosteroids have been recommended to avoid unnecessarily prolonged courses of steroids in patients who do not relapse.[107] Macrolide antibiotics[154–156] and steroid-sparing agents such as cyclophosphamide, azathioprine, or rituximab[157–159] have been used as alternative immunosuppressants for individuals with COP or secondary OP. However, the clinical utility of these approaches has not been completely validated. It is not known whether individuals with secondary causes of OP experience different long-term outcomes from individuals with COP. While most COP patients have favorable prognosis, a subset of patients present with a rapidly progressive and fatal form of OP. Some investigators suggest such cases represent an overlap group with acute interstitial pneumonia or acute respiratory distress syndrome (ARDS). Nonetheless, the literature does suggest that a small subgroup of COP patients suffer a progressive fibrotic course. Alternative forms of immunosuppression such as cyclophosphamide have been used in such rapidly deteriorating patients, although experience with this approach is at best limited and the clinical utility is not entirely clear.[157]

ACUTE/SUBACUTE INTERSTITIAL PNEUMONIA: ACUTE INTERSTITIAL PNEUMONIA

The original description of acute interstitial pneumonia dates back more than 75 years. Clinical hallmarks of this entity are described below.

■ Definition and Historic Perspective

Acute interstitial pneumonia, also called "AIP" or "Hamman–Rich syndrome," was first described by Hamman and Rich in 1935 and is a rare and fulminant IIP.[160] Current ATS/ERS diagnostic criteria for AIP include the following:[23] (1) rapidly progressive clinical course (≤2 months) leading to respiratory failure; (2) exclusion of infectious, toxic, autoimmune, or any other known cause of ARDS; (3) diffuse alveolar damage (DAD) on biopsy specimens (see below); (4) radiologic findings consistent with ILD; and (5) absence of chronic lung disease.

■ Clinical Presentation

AIP is quite rare and most frequently presents in previously healthy individuals with no prior lung disease. The disease has no sex predominance and most commonly affects patients more than 40 years old with a mean age of 50 to 55 years.[161–163] Unlike most other IIPs,[161] AIP typically presents with an acute onset of fever (75%), cough (70%), and rapidly progressive dyspnea (90%)[105] with many patients reporting the sensation of an infectious prodrome. Most patients are hypoxemic upon presentation and rapidly progress to respiratory failure requiring mechanical ventilation. Physical examination frequently reveals tachypnea and bilateral crackles in all lung fields. Signs of chronic lung disease such as clubbing are uncommon and argue against a diagnosis of AIP, while the presence of skin or joint abnormalities might suggest an underlying autoimmune process. While initial management focuses on stabilizing respiratory status, diagnostic evaluation should be undertaken. Once cardiogenic pulmonary edema has been ruled out by electrocardiogram, cardiac enzymes, and echocardiogram, causes of noncardiogenic pulmonary edema and ARDS should be investigated. Given the broad array of diseases and exposures associated with the development of ARDS, this assessment should include careful exposure history including medications and occupational hazards, as well as a complete rheumatologic history. The serologic and muscle enzyme testing described earlier for NSIP may also be valuable in this setting.

■ Underlying Associations

The differential diagnosis of AIP is broad and includes left heart failure, diffuse alveolar hemorrhage, OP, hypersensitivity pneumonitis, acute exacerbation of UIP/IPF, and DIP. AIP can generally be distinguished from these entities by careful history, examination of chest radiography, and ancillary tests described earlier. Once the AIP diagnosis has been established, it is imperative to seek underlying causes including collagen vascular disease such as antisynthetase syndrome[164] or lupus;[165] therapeutic exposures such as certain chemotherapies, biologic therapies, radiation, and hyperoxia;[166,167] illicit drugs such as heroin or cocaine;[168] toxic exposures such as smoke inhalation and other gases;[166] massive transfusion;[169] fat embolism; aspiration;[170] and infections such as atypical pneumonias (*Mycoplasma*[171] or *Legionella*[172]) and viral infections (influenza).[173] AIP should also be differentiated from acute exacerbations of underlying IIPs or other pre-existing forms of underlying lung disease.

■ Pulmonary Function Testing

Most patients are too ill to undergo pulmonary function testing, but a restrictive ventilatory defect and impaired diffusion capacity would be expected.

■ Chest Imaging

AIP is radiographically and pathologically indistinguishable from ARDS. Imaging findings depend upon whether the early, exudative phase or chronic, fibrotic phase is present. Diffuse consolidation and ground-glass opacities are typically seen in the early exudative phase, with the dependent areas of lung being more affected.[20,23,174,175] The early, exudative phase is difficult to distinguish radiographically from other entities such as cardiogenic or noncardiogenic edema, diffuse infection, or hemorrhage. In patients who survive the acute phase (sometime after the first week), in addition to the lung consolidation, findings of underlying fibrosis such as

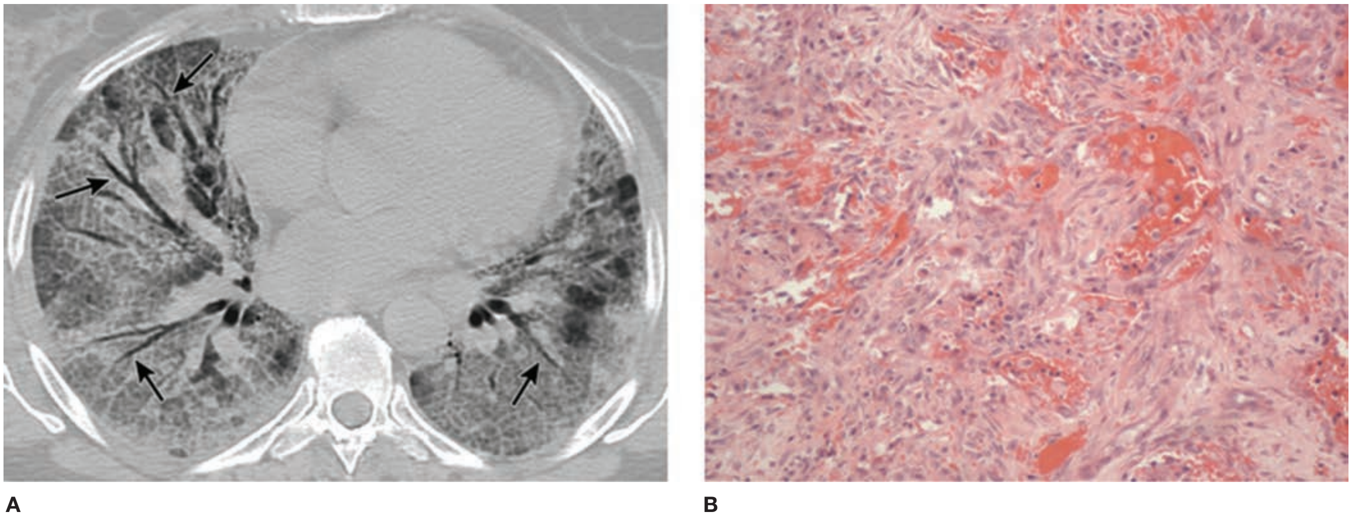

Figure 55-6 A 45-year-old female with acute shortness of breath. High-resolution CT image through the thorax (**A**) demonstrates diffuse ground-glass opacities involving every lobe. Within areas of ground-glass opacity are reticular markings and traction bronchiectasis *(arrows)* suggestive of organization and underlying fibrosis. Lung tissue obtained at autopsy revealed findings of diffuse alveolar damage, which included obliteration of the alveolar space with structural cell death responses, acute inflammation, and hyaline membrane formation (**B**). *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

architectural distortion and traction bronchiectasis with or without honeycombing become apparent on imaging, and are usually more severe in the nondependent portions of the lung (Fig. 55-6).[20,23,175]

■ Pathology

If microbiologic testing yields negative sputum culture and viral studies, bronchoscopy with BAL should be performed to rule out undiagnosed infection or alternate diagnosis. There is generally no role for transbronchial biopsy in the diagnosis of AIP; surgical lung biopsy is the preferred approach if tissue diagnosis is required. A pathologic diagnosis of DAD demonstrates diffuse and extensive cell death accompanied hyaline membranes, which are histologically apparent layers of fibrin mixed with necrotic epithelium. This material lines the alveolus and reflects the severity and acuity of the injury (Fig. 55-6). As the injury progresses, it evolves into its organizing phase, which can either resolve into relatively normal lung or result in lung fibrosis.

■ Clinical Course and Outcomes

The fulminant and often untreatable nature of AIP endows this disease with a particularly high mortality. More than 50% of patients die during hospitalization and most patients die within 6 months of diagnosis. Those who survive are at risk for disease recurrence or the development of other forms of ILD. However, a small fraction of survivors may experience complete recovery of lung function.[162,176] Treatment is detailed below and is aimed at supporting the patient and attempting to limit the acute injury and inflammation.

■ Therapy: Nonpharmacologic

The mainstay of therapy for AIP is supportive care.[162] This includes supplemental oxygen or mechanical ventilation, adequate sedation, nutritional support, and prevention of ICU-related complications such as stress-induced ulcers, venous thromboembolism, catheter-related bloodstream infections, and ventilator-associated pneumonias.

■ Therapy: Pharmacologic

High/pulse-dose glucocorticoid therapy is frequently administered to patients suffering from AIP, but, due to the rarity and often grave nature of AIP, there have been no clinical trials assessing efficacy of this treatment.[162] Therefore, the evidence supporting this approach is anecdotal and is, in fact, based on case reports that showed a conflicting survival benefit.[161,162,177] For example, in the largest case series published in 1990, of 29 patients treated with glucocorticoids, survival was 45% in the treated group versus 33% in the untreated group.[161] Similarly, in a smaller series of only 8 patients treated with pulse-dose steroids, 7 patients survived.[177] Conversely, a different study of 9 patients treated with 8 mg/kg of methylprednisolone found a mortality of 100% with this regimen.[162] Despite this lack of clear benefit, expert opinion recommends continuation of high-dose steroids for several days followed by a maintenance dose of the equivalent of prednisone 60 mg/day that can be tapered over the ensuing weeks if the patient survives.[162]

The side effects of high-dose steroids cannot be overstated. In addition to the long-term side effects described earlier, short-term risks in the ICU include hyperglycemia, immunosuppression, neuromuscular complications, and delirium. Thus, in some settings when steroids are contraindicated or a steroid-sparing agent is required, practitioners might employ a trial of non-steroid-based therapy. Use of other agents such as azathioprine, cyclosporine,[178] cyclophosphamide, and vincristine have been reported in AIP, but these agents are not recommended for routine use.[170] OLT has been successful in several patients with respiratory failure attributed to AIP. However, because these patients are frequently too unstable for transfer to a transplant center, the utility of OLT in AIP is at best limited.

LYMPHOID INTERSTITIAL PNEUMONIA

Rare idiopathic interstitial pneumonias include lymphocytic interstitial pneumonia, discussed below, and pleuroparenchymal fibroelastosis, discussed subsequently.

■ Definition and Historic Perspectives

In 1969, Liebow and Carrington developed the term *lymphoid interstitial pneumonia (LIP)* to describe a benign polyclonal infiltration of the alveolar space and interstitium with mature B or T cells. LIP exists within a spectrum of lymphoproliferative disorders affecting the lung and, as such, its classification as an IIP has been debated. Furthermore, the malignant potential of LIP is not well defined[179,180] but all sources agree that identification of monoclonal features effectively rules out LIP and points to a malignant etiology.[181,182] However, because the clinical and radiographic features overlap with the other IIPs in terms of differential diagnosis[183] and treatment approach, the most recent ATS and ERS statement on IIPs retained LIP within this classification.[20,23] LIP is also sometimes seen in children; however, because this chapter addresses adult IIPs, pediatric LIP will not be discussed.

■ Clinical Presentation

Given its rarity, the demographics of LIP are difficult to define but available data indicate that mean age of onset is during the fifth decade of life, and the diagnosis is more common in women.[23,184] LIP typically presents as slowly progressive cough and dyspnea over several years.[184] Systemic symptoms are rare, but fever, weight loss, chest pain and joint aches have been reported.[23,184] Chest auscultation may be normal or may reveal crackles as the disease progresses.[185] Extrapulmonary findings may include lymphadenopathy or joint findings consistent with underlying Sjögren syndrome or RA. Findings consistent with severe lung disease, such as clubbing, are rarely detected.[23] Laboratory examination may reveal mild anemia. Quantification of serum immunoglobulins reveals either a polyclonal gammaglobulinemia or a monoclonal increase in either IgG or IgM in up to 75% of patients.[182,186] Immune complexes are sometimes seen, but only infrequently.[187]

■ Underlying Disease Associations

Most cases of LIP are associated with an underlying cause, such as Sjögren syndrome,[188] or immunodeficiency, such as severe combined immunodeficiency and HIV.[8,118,153,189] LIP has also been reported with RA,[190] Hashimoto disease,[191] pernicious anemia,[192] chronic active hepatitis,[193] systemic lupus erythematosus,[194] autoimmune hemolytic anemia,[186] primary biliary cirrhosis,[182] and hypogammaglobulinemia.[192,195] LIP is also seen in certain viral infections including Epstein–Barr[196,197] and human T cell lymphotropic virus type I (HTLV-I).[198,199] Truly idiopathic LIP accounts for less than 20% of cases.[184] Thus, as with NISP, a diagnosis of LIP should prompt a dedicated search for an underlying cause.

■ Pulmonary Function Testing

When present, abnormalities include a restrictive defect characterized by reduced FVC and TLC, an impaired $D_{L_{CO}}$, and, potentially, hypoxemia.[200]

■ Chest Imaging

The imaging findings of LIP are variable and depend upon the underlying disease process. The chest radiograph reveals nonspecific findings such as bilateral reticular markings and hazy, ground-glass opacities. As with the other IIPs, LIP is much better characterized by HRCT. Diffuse, patchy, or lower lobe predominant ground-glass opacities with reticular markings and small cysts is the pattern most commonly seen on CT in patients with HIV, and can be difficult to distinguish from viral or opportunistic infections such as pneumocystis or CMV pneumonia.[20,201] Thickened bronchovascular bundles, septal thickening, and centrilobular nodules are less commonly present. LIP in patients with Sjögren syndrome typically manifests as bilateral, thin-walled cysts of varying sizes (but usually larger than the cysts seen in HIV-associated LIP) scattered throughout the lungs with intervening normal lung parenchyma (Fig. 55-7).[23] Often, a vessel appears to be associated with (or adjacent to) the wall of a cyst, thus the term "perivascular cyst." Ground-glass opacities may exist as well.[23,183,202] The main differential diagnosis for this appearance would include other causes of cystic lung disease, such as lymphangioleiomyomatosis (in a female patient), Langerhans cell histiocytosis (in a cigarette smoker), and *Pneumocystis* pneumonia (in immunocompromised patient), although the latter two entities usually manifest with upper lobe–predominant cysts.

■ Pathology

LIP pathology demonstrates a dense interstitial lymphoid infiltrate containing lymphocytes, plasma cells, and histiocytes, in combination with type II cell hyperplasia (Fig. 55-7). The alveolar septa are extensively infiltrated. Lymphoid follicles with germinal centers are often seen.[23,182] Honeycombing and nonnecrotizing granulomas are sometimes detected[23,182] along with intra-alveolar organization and macrophages, but when these latter aspects are the dominant pathologic feature, the diagnosis of LIP should be reconsidered.[23]

■ Natural History, Clinical Course, and Treatment

Little is known about the clinical course and prognosis of LIP. The results of several case series suggest that approximately 50% of patients improve, 10% remain stable, and 40% will die of disease within 2 years, even when treated with immunosuppression.[23,182,184,203] Those patients who survive are subject to a small but significant chance of progression to pulmonary lymphoma[182] in addition to an increased risk of serious and potentially fatal infections related either to the underlying cause of LIP (inherited or acquired immunodeficiency) or to the immunosuppressive therapies used to treat this disease.

Idiopathic LIP

Treatment for LIP depends in part upon the patient's symptoms and the underlying cause. Asymptomatic patients with mild, idiopathic disease are typically subject to careful longitudinal follow-up with serial PFTs and chest imaging because a small percentage of these patients will spontaneously improve.[23] Patients who deteriorate over time, or those who are highly symptomatic or significantly impaired upon initial diagnosis, are offered treatment with immunosuppression. While no data exist regarding the safety or efficacy of glucocorticoids in patients with idiopathic LIP,[23] extrapolation of case series of patients with CTD-associated LIP (in which approximately 50% of patients show some evidence of response) suggests potential benefit.[203] Patients are typically started on the equivalent of 1 mg/kg (ideal body weight) oral prednisone for 8 to 12 weeks, after which chest imaging and PFTs are repeated. Those patients who demonstrate an objective response may continue their prednisone at a tapered dose for several months longer; those who do not respond generally discontinue therapy or are offered an alternate disease-modifying agent such as cyclosporine or azathioprine. Again, it should be noted that the evidence for this approach is scarce and the risk of side effects, and possible lack of efficacy, must be weighed against the potential benefit inherent in this class of drugs. In addition, patients on long-term steroid therapy should be offered prophylaxis against *Pneumocystis* pneumonia and should be monitored for bone health.

Nonidiopathic LIP

Management of LIP in the setting of CTD is similar to that of idiopathic LIP, but the use of immunosuppression in this population is based on stronger evidence.[184,203] Treatment of LIP in the setting of HIV usually involves initiation of highly active antiretroviral therapy (HAART), as in many patients this intervention will reduce symptoms and improve both radiographic disease burden and lung physiology.[204–206] For patients whose disease persists despite use of HAART, glucocorticoids are commonly used, although evidence for this regimen precedes the HAART era.[200,207] As with idiopathic and CTD-related LIP, *Pneumocystis* prophylaxis should be strongly considered for patients with HIV-related LIP who are treated with immunosuppression.

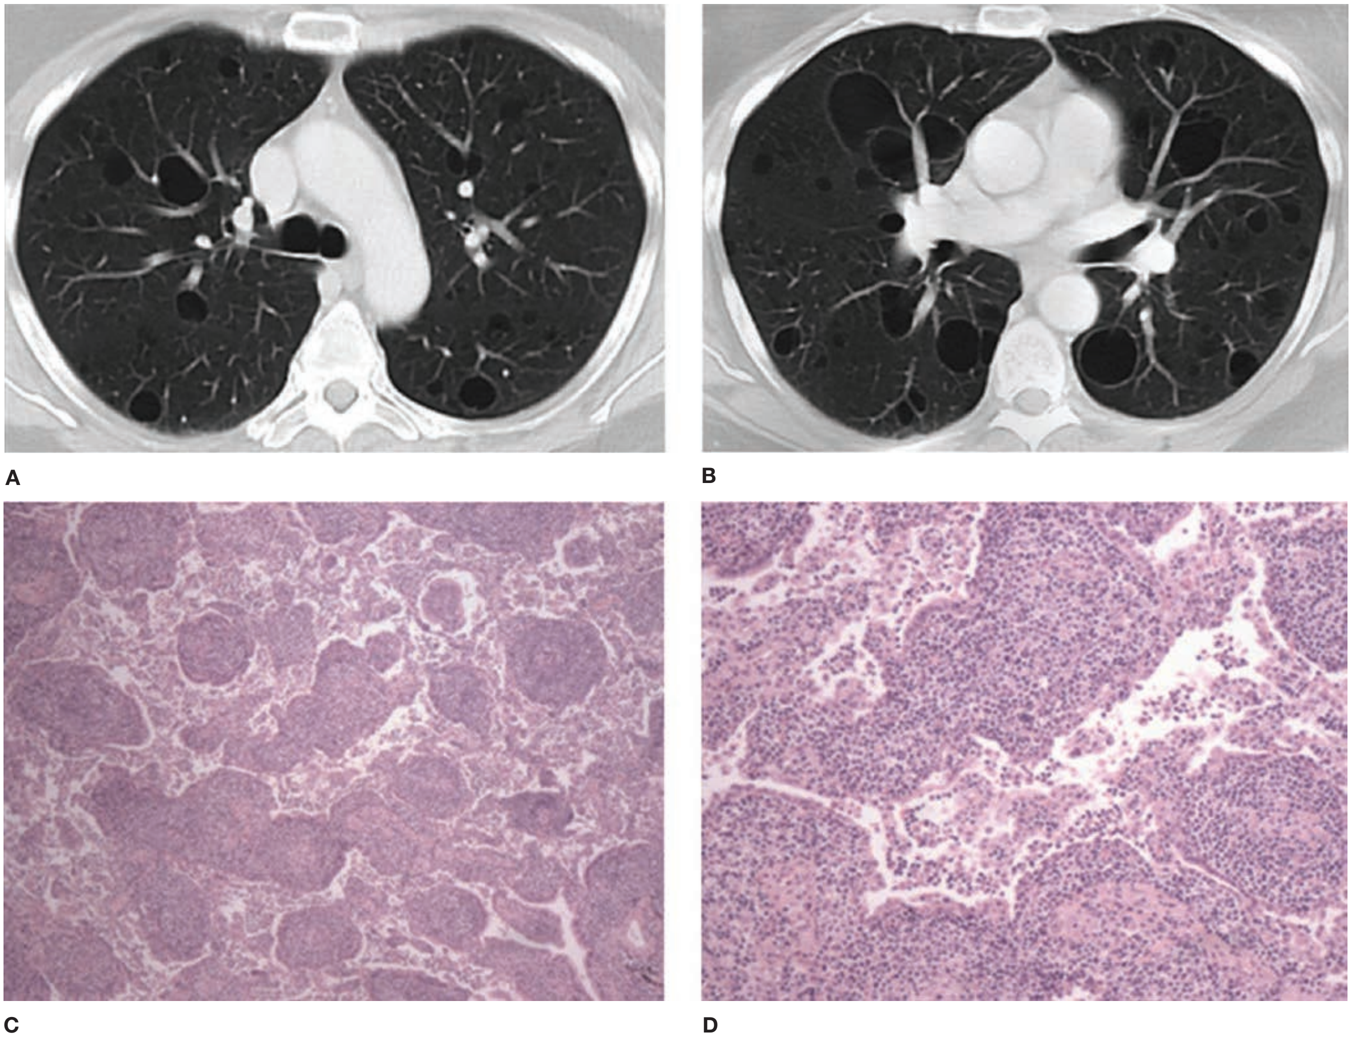

Figure 55-7 A 51-year-old female with Sjögren syndrome and lymphocytic interstitial pneumonia (LIP). Axial CT images through the upper (**A**) and mid (**B**) thorax show multiple thin-walled cysts of varying sizes bilaterally involving the upper and lower lobes. Note the presence of normal lung parenchyma between the cysts. Low- and high-power views (**C, D**) of LIP lung tissue reveal a dense interstitial infiltrate containing lymphocytes, plasma cells, and histiocytes, combined with type II cell hyperplasia and increased alveolar macrophages. *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

IDIOPATHIC PLEUROPARENCHYMAL FIBROELASTOSIS

More than 20 years prior to its formal designation as an independent form of rare idiopathic interstitial pneumonia, a unique pattern of upper lobe–predominant lung disease characterized by pleural and parenchymal fibroelastosis was described in the literature. In 2004, Frankel first used the term *pleuroparenchymal fibroelastosis (PPFE)* to describe five cases who shared this previously uncategorized pattern of fibrosis, which also closely resembled the pulmonary upper lobe fibrosis (PULF) proposed by Amitani et al. in 1992.[1] Now, years later, it is accepted that PULF and PPFE represent the same entity, and PPFE was formally recognized as a specific independent form of rare idiopathic interstitial pneumonia by the ATS/ERS in 2013.[1] Idiopathic PPFE is reported to account for approximately 6% to 8% of all ILD,[208] but due to a lack of formal established diagnostic criteria and subsequent misdiagnosis, the true incidence and prevalence for PPFE is unknown. It usually is idiopathic, but has been linked to other diseases, as described below.

■ Clinical Presentation

PPFE is a rare disease. However, as imaging modalities improve and awareness increases, it is being diagnosed more frequently. Age of presentation is highly variable, ranging from age 8 to 87 in the literature,[209,210] distributed bimodally, with a smaller peak occurring in the third decade of life and a larger peak occurring around the sixth decade.[211] The idiopathic form generally presents during middle age, without sex difference.[1] Some reports identified a female predominance (especially among the young),[212] but other studies have not demonstrated a difference between the sexes.[213–215] Mean time from development of symptoms and diagnosis is usually 2 to 3 years.[216,217] Presenting symptoms for PPFE commonly include dyspnea with cough, similar to other ILDs, accompanied by weight loss that worsens with disease progression. Chest auscultation may be normal initially, with crackles once PPFE has extended beyond the upper zones, or if there is coexisting UIP, NSIP, or hypersensitivity pneumonitis (HP). Notably, due to volume loss in upper lobes, a large number of patients with PPFE develop platythorax, flattening of the chest associated with a reduced anteroposterior diameter, which can be noticed as the deepening of the suprasternal notch on physical examination.[218] Pneumothorax, which can be asymptomatic and recurrent, is a complication in both idiopathic and secondary disease.[219] Clubbed fingers occur in less than 25% of patients with PPFE.[212]

There are no diagnostic laboratory tests for PPFE. Some patients have elevated biomarkers for Krebs von den Lungen 6 (KL-6) antigen[220–222] and surfactant protein D (SP-D).[221] A recent study found elevated levels of urinary desmosine in individuals with biopsy-proven PPFE, but this has not yet been validated for clinical application.[223]

■ Underlying Associations

Little is known about the etiology of PPFE, and most cases are considered idiopathic without associated underlying conditions. Common secondary causes of PPFE include history of prior hematopoietic stem cell[224,225] or lung transplantation.[226] PPFE has also been described to resemble a form of chronic graft-versus-host disease in bone-marrow transplant recipients.[227–230] A few cases have occurred amongst siblings, suggesting a possible underlying genetic predisposition.[231] Specific mutations in telomere regulating genes (telomere reverse transcriptase and telomerase RNA) have been identified among those diagnosed with PPFE and are associated with more progressive disease.[210,232] A causal relationship between the development of PPFE and prior treatment with amiodarone[233] or chemotherapy (alkylating agents carmustine and cyclophosphamide) has been explored in the literature.[234] PPFE is also associated with autoimmune diseases (RA, ankylosing spondylitis, ulcerative colitis)[235,236] as well as infection (*Aspergillus*, *Mycobacterium avium intracellulare*).[237,238] Environmental exposures, including aluminosilicate dust and asbestos, have been implicated, but no association with cigarette smoking has been established.[213,239] PPFE can occur independently or coexist with other patterns of fibrosis, including UIP and HP.

■ Pulmonary Function Testing

A restrictive ventilatory defect, characterized by a reduction in TLC, decreased FVC, and increased FEV_1/FVC ratio, is generally present in PPFE, accompanied by decreased DL_{CO}. However, mixed ventilatory defects also can be found.[227] In a subset of patients, residual volumes also may be reduced; the cause for this remains uncertain, but is hypothesized to occur due to increased end-expiratory air trapping or inhomogeneous lung emptying. FVC may decline rapidly following diagnosis; this decrease is especially marked in those with telomere gene abnormalities.[210] Platythorax may also contribute to ventilation perfusion mismatch as the disease progresses.[213]

■ Chest Imaging

In early stages, bilateral irregular thickening of apices may be the only abnormality on an otherwise normal chest radiograph. As the disease progresses, reticular and nodular opacities appear in the upper lung fields accompanied by bilateral hilar opacities; lateral views may demonstrate narrowed anterior-posterior dimensions.[213] On HRCT, early stages of the disease presents with apical subpleural and reticular opacities, with characteristic sparing of other lung fields. As the disease progresses, elevated hilar shadows with parenchymal thickening with fibrosis become more pronounced, with the development of traction bronchiectasis, bullae, and large cysts, with or without air bronchograms, and volume loss (Fig. 55-8). Specific radiologic criteria for the definitive diagnosis of PPFE on CT were proposed by Reddy et al. in 2012,[216] requiring the presence of upper lobe pleural thickening with subpleural fibrosis, and limited lower lobe involvement. Other patterns of fibrosis, including HP, UIP, and NSIP, can also coexist with PPFE, with their respective findings on imaging.[217,240,241]

■ Pathology

A multidisciplinary approach is critical to the diagnosis of PPFE, with consideration of radiologic and clinical data, and confirmation by pathologic data if necessary. When the clinical presentation and imaging are insufficient for a confident diagnosis of PPFE, nonsurgical sampling with transbronchial and transthoracic biopsies can be obtained. Surgical lung biopsy also can be employed, but it is often avoided if possible due to concerns for complications, or contraindications in secondary PPFE. Characteristic histology of PPFE includes upper lobe–predominant fibrotic and elastotic changes in lung parenchyma, subpleural intra-alveolar fibrosis and elastosis (IAFE), and visceral pleural fibrosis. IAFE pathology is not exclusive to PPFE and can be found in injuries following toxicity (paraquats), radiation, and ARDS, as well as "apical cap." Both UIP and HP have been shown to coexist with PPFE.[242] UIP is most common, occurring most frequently in the lower lobes. IAFE shares similar features with UIP, including its subpleural nature and foci of fibroelastic proliferation at the interface between areas of fibrosis and normal lung parenchyma, with sparse or nonspecific inflammation. However, in addition to lacking honeycomb change, fibrosis in PPFE is accompanied by preserved alveolar structure with elastin fiber deposition leading to homogenous intra-alveolar fibrosis (Fig. 55-8). Utilization of elastic Van Gieson stain to highlight elastic fibers will show marked elastin deposition around the alveolar walls, versus a more disorganized and sparse pattern in fibrotic areas in UIP.[243] PPFE can be distinguished immunohistochemically from UIP through the positive staining of myofibroblasts for podoplanin.[244] PPPE has also been reported in patients diagnosed with chronic HP. The presence of granulomas on biopsy histology (found in approximately 15% of cases)[209,216,242,245] is associated with better prognosis, but possibly due to coexistence of an additional inflammatory process (such as HP, or infection) that is more responsive to treatment. Thus far, a factor to distinguish between primary and secondary PPFE has not been found.

■ Clinical Course and Outcomes

The prognosis for PPFE is poor. Once regarded as slowly progressing with an insidious course, a second phenotype of disease with rapid progression also has been described. Most patients experience disease progression following diagnosis, with mean survival ranging from 4 months to 11 years.[213,220,246,247] Survival rates at 1, 3, and 5 years are 88.5%, 45.5%, and 28.9%, respectively.[217,248] Patients with iPPFE, genetic mutations affecting telomere lengths, and coexisting UIP or HP may be more susceptible to rapidly progressive disease. Studies evaluating the effects of coexisting UIP on outcomes have had mixed results,[247,249] while PPFE is associated with higher mortality in patients with coexisting chronic HP.[240] As the clinical course is often progressive, bilateral lung transplantation may be the only definitive treatment.[250–254]

■ Pharmacologic Therapy

There are no effective pharmacologic treatments for PPFE. Prednisone in low doses may be helpful; higher doses of corticosteroids and other immunosuppressive agents (azathioprine, methotrexate) may increase infection risk.[212] In PPFE occurring in restrictive allograft syndrome (RAS), the antifibrotic agent pirfenidone has been used with varied results.[255,256] Data from the INBUILD trial suggest that nintedanib may have a role for patients with non-IPF progressive fibrotic ILD[63] and so could be considered in patients with PPFE. A retrospective case series demonstrates that pirfenidone may be effective in slowing disease progression as measured by FVC in PPFE patients with evidence of coexisting UIP pattern.[257] Antibiotic therapy or antifungal therapy for those prone to infection should be considered when indicated.

UNCLASSIFIABLE INTERSTITIAL PNEUMONIA

Despite advances in radiographic investigation and thorough multidisciplinary evaluation, some ILD cases cannot confidently be diagnosed, prompting the proposal of an "unclassifiable" subgroup of IIP

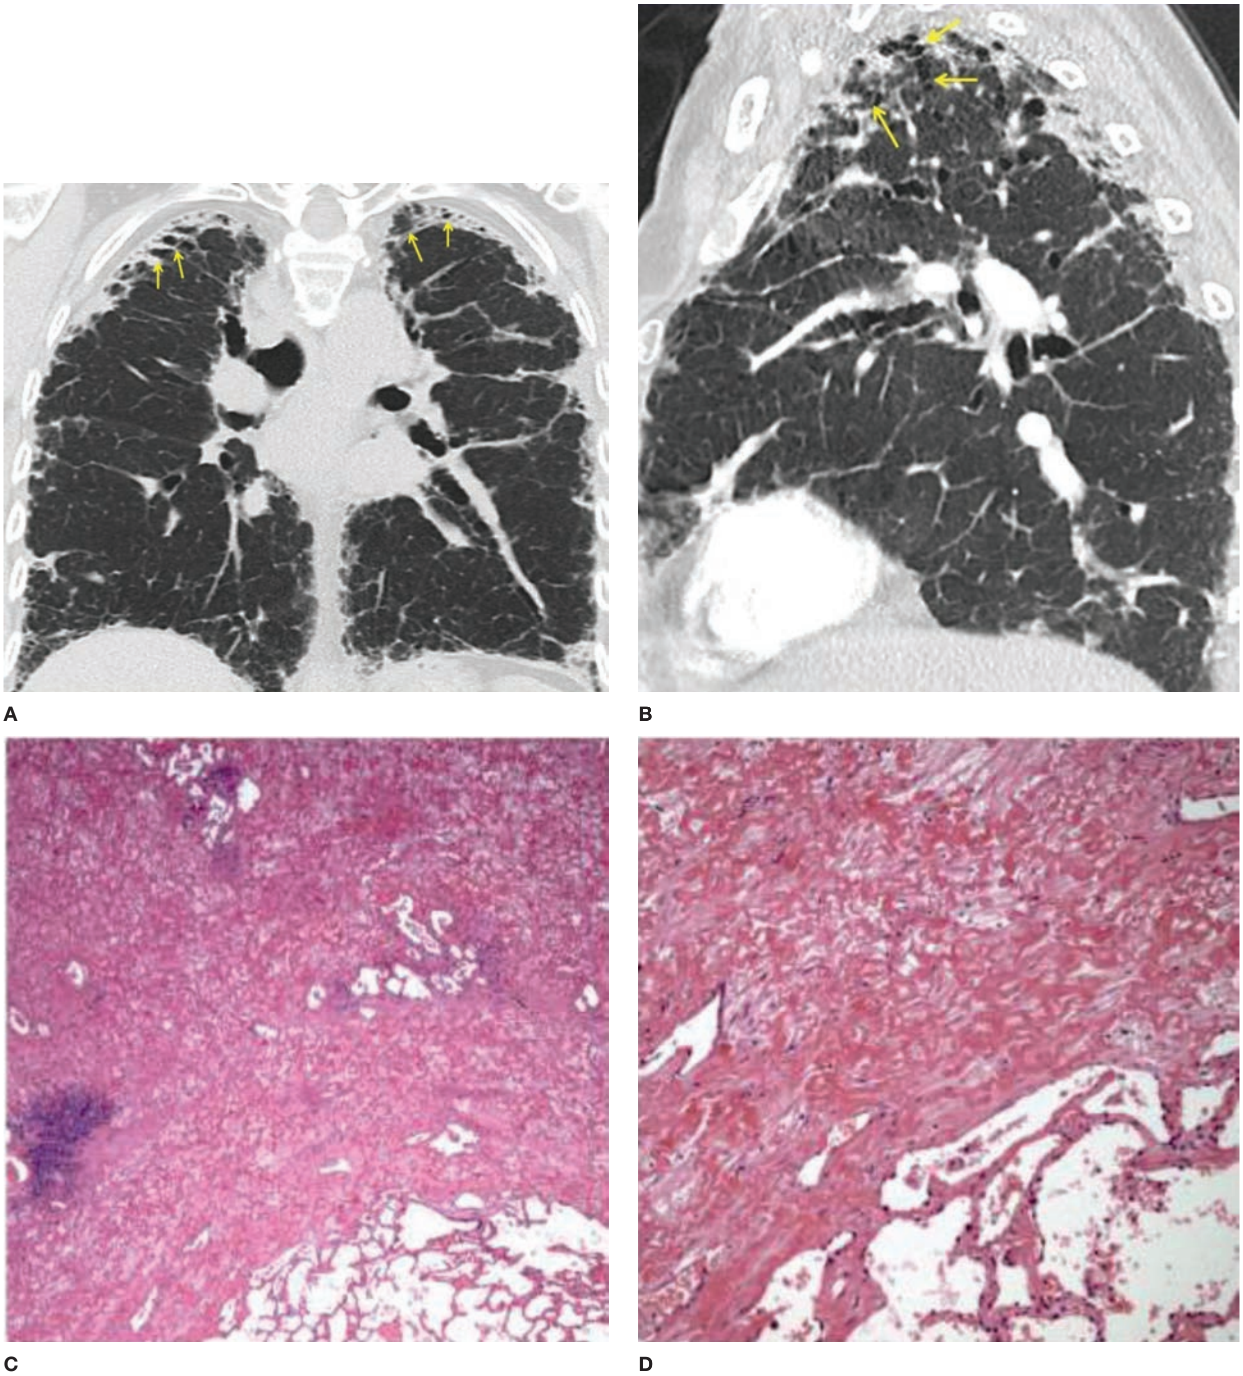

Figure 55-8 73 year old female with progressive dyspnea and pleuroparenchymal fibroelastosis (PPFE). Coronal (**A**) and sagittal (**B**) reformatted CT images demonstrate bilateral, peripheral, upper lobe predominant pleural thickening with subjacent consolidation containing fibrotic changes including traction bronchiectasis *(arrows)*. The lung parenchyma is diffusely effaced by fibroelastosis with no recognizable lung parenchyma (low-power view) (**C**). Note that conventional honeycombing (mucus filled terminal airways) is not seen. (**D**) Fibroelastosis consists of unusual extracellular matrix with both fibrosis (pink fibers) and elastic fibers (bluish-gray) (high-power view). No inflammation is present. *(Pathology images reproduced with permission from Robert J. Homer, MD, PhD, Yale School of Medicine.)*

in 2002[23] and later inclusion of "unclassifiable IIP" as a distinct entity in the ATS/ERS consensus statement on classification of IIPs in 2013.[1] As outlined by the consensus statement, circumstances that warrant labelling a condition as unclassifiable include situations in which there are discrepancies between investigative findings, there are inadequate data (most commonly due to lack of biopsy), there is a discordance between findings (either in the presence of coexisting disease or where different biopsy sites show different pathologic findings), when prior treatment makes interpreting diagnostic information impossible (for instance, biopsy results showing NIP following the use of glucocorticoid treatment for DIP),[258] or when conflicting pathologic patterns are present on HRCT.[1] Other causes for "unclassifiable IIP" designation include the discovery of a new entity or atypical presentation of a previously recognized entity. In the literature, the reported prevalence of unclassifiable disease is 12% of all ILD, but many of the studies used to compute this data point were published prior to the use of HRCT.[259] Similarly, it is difficult to determine if these cases are truly unclassifiable, versus not yet classified, as many patients are unable to undergo surgical lung biopsy due to contraindications or increased risk for complications.

Clinically, patients report dyspnea and fatigue on presentation, with physical exam findings notable for Velcro rales.[260] While there are no tests available to distinguish between IIPs, advances in biomarker and genetic testing may one day allow for a definitive diagnosis in the future. Different approaches, including cryobiopsy, are being evaluated, which may enable histology sampling in those who would otherwise have contradictions to undergoing diagnostic surgical biopsy.[261–263] There is no standardized pharmacologic treatment for unclassifiable ILD, and therapeutic regimens are individualized based on the degree of inflammation or whether fibrosis is deemed present.

CONCLUSION

The non-IPF IIPs are characterized by diverse presentations, underlying associations, natural history, and response to therapy. Given the complexity of diagnosis and management, these diseases are best managed by highly experienced practitioners using a multidisciplinary approach.

CHAPTER 56

Hypersensitivity Pneumonitis

Prerna Mota
Richard I. Enelow

DEFINITION

Hypersensitivity pneumonitis (HP) is an interstitial lung disease believed to be mediated by aberrant cellular and humoral immune responses to various inhaled antigens in susceptible individuals, resulting in inflammatory and/or fibrotic disease of the lung parenchyma and small airways. Its clinical presentation and natural course can be quite variable, and despite the efforts of numerous expert groups and panels, clear consensus on diagnostic criteria and common nomenclature has proven elusive. Previous classification schemes described "acute HP" and "chronic HP" as two forms of the disease, the latter temporally related to the former, despite limited evidence to support this approach. The recognition that prognosis is minimally related to disease duration, and is more dependent upon extent of fibrosis, has led to the recent move to reclassify HP subtypes as "nonfibrotic HP" and "fibrotic HP." The latter represents a uniquely challenging entity, for multiple reasons discussed below.

EPIDEMIOLOGY AND ETIOLOGIES

The prevalence of HP is quite variable in different populations, presumably because of differing intensity, frequency, and duration of inhalation exposure, probable variations in environmental and occupational patterns, and heterogeneity in host susceptibility (genetic or otherwise). A large number of antigenic exposures are associated with HP, as shown in Table 56-1. At the same time, prevalence data are colored by the variability of diagnostic criteria and the absence of a clear gold standard.[1] Once thought to be a relatively rare disease, HP (by any definition) is becoming more frequently recognized, as awareness of the limitations of classic diagnostic criteria has grown. Available studies suggest an overall incidence of HP of 0.3 to 0.9 per 100,000 individuals,[2–5] with striking differences in specific populations studied. These data on incidence and prevalence largely pertain to acute (or nonfibrotic) HP, as an entity more easily recognized particularly in association with identifiable antigen exposure. The nuances of this designation, and those of the less recognizable chronic (or fibrotic) entities, will be discussed below.

The most commonly reported form of HP is bird-related, with reports suggesting that 5% to 15% of pigeon breeders (members of pigeon-breeding clubs who participated in surveys) exhibit evidence of HP, so-called pigeon breeder's disease.[6,7] Bacterial and fungal antigens (associated with "farmer's lung," "humidifier lung," and "summer-type HP") are relatively common in selected populations, although they vary widely in frequency in different regions of the world.[8–12] The frequency of disease in Finnish farmers, for example, has been reported as high as 5% to 10%.[12]

Recognition of new examples of HP often requires a cluster of new cases with a unifying exposure history. For instance, occupational exposure to nontuberculous mycobacteria (NTM) in metalworking fluids was discovered in a cluster of machinists with HP.[13] Since complete occupational and avocational histories are frequently not obtained from patients presenting with interstitial pneumonia, it is likely that there are more exposures that cause HP that have not yet been recognized and described.

CLINICAL FEATURES

HP has long been categorized as acute, subacute, or chronic, although the distinctions have not always been well defined (particularly the vague notion of "subacute" disease), and heterogenous clinical presentations are frequent in all forms of HP. As such, a two-cluster solution has been proposed by several groups to better characterize the subtypes of disease:[14,15] acute (usually associated with more recurrent systemic symptoms, often with a normal chest radiograph) and chronic (usually associated with greater restriction, hypoxemia, and radiographic evidence of fibrosis). The most readily recognizable form is an acute presentation of HP, in which patients often present with a flulike illness 4 to 12 h after exposure to an offending antigen. The physical examination may be notable for crackles, mid-inspiratory squeaks (chirping rales or squawks), and occasional hypoxemia. A more indolent presentation is the rule for "chronic HP," which is usually characterized by features similar to any chronic interstitial lung disease, including gradual onset, progressive dyspnea, and crackles on examination, often with digital clubbing.[16] However, there is considerable overlap in the acute and chronic presentations of HP, and it remains controversial whether a temporal relationship exists between acute and chronic forms of disease, or if serial evolution occurs between the two.[17] Furthermore, chronic/fibrotic HP can be easily mistaken for other forms of idiopathic interstitial pneumonia, especially since the inciting exposure may remain unknown in about 50% of patients despite a careful history.[18]

In the evaluation of a patient with suspected HP, a thorough history of occupational, avocational, and environmental exposures should be taken, high-resolution chest CT scanning should be obtained, analysis of IgG precipitins is often performed, and if an actionable working diagnosis is not established, biopsy of lung tissue may be required. Even after histopathology is obtained, diagnostic challenges often remain, as in circumstances when the clinical picture, the radiographic evidence, the laboratory data, and the pathology may be *compatible* with the diagnosis but not *typical*. The potential added value of multidisciplinary discussion has been emphasized by numerous expert panels.[15,18–20]

DIAGNOSIS

An attempt at greater rigor and consistency in the diagnostic criteria of HP was made by several joint society committees, with an aim toward more definitive diagnosis.[18,19] The classification of HP into acute, subacute, and chronic has been proposed to be replaced by two categories, nonfibrotic and fibrotic HP. (Subacute had been generally dismissed already as a subtype.) The practical value of this distinction is evident in the clear association of fibrosis (radiographic and/or histologic) with worse prognosis. The designation of radiographic and histopathologic criteria into "typical, probable, and indeterminate" serves to codify the degree of certainty (or more generally uncertainty) of the diagnosis, although there is no consensus level of certainty necessary to proceed with treatment based upon a provisional diagnosis. The utility of seemingly refined diagnostic criteria (when the quality of evidence and confidence in estimated effects of each recommendation are individually very low) is not clear in clinical settings, but despite their arbitrary nature, the criteria are likely to be useful in the design of future clinical trials. Nevertheless, it is important to consider that while the duration of symptoms in HP is not associated with survival time, the extent of fibrosis is an important predictor.[21]

In clinical practice, the three most important realms for diagnosis include (1) attempted identification of antigen exposure; (2)

TABLE 56-1 Etiologies of Hypersensitivity Pneumonitis

Disease	Antigen Source	Probable Antigen
Farmer's lung	Moldy hay	Thermophilic actinomycetes (*M. faeni* [*S. rectivirgula*], *T. vulgaris*) *Aspergillus* spp.
Bagassosis	Moldy pressed sugarcane (bagasse)	Thermophilic actinomycetes (*T. sacchari*, *T. vulgaris*)
Mushroom worker's disease	Moldy compost and mushrooms	Thermophilic actinomycetes (*M. faeni*, *T. vulgaris*) *Aspergillus* spp. Mushroom spores
Suberosis	Moldy cork	*Penicillium* spp.
Malt worker's lung	Contaminated barley	*Aspergillus clavatus*
Maple bark disease	Contaminated maple logs	*Cryptostroma corticale*
Sequoisis	Contaminated redwood sawdust	*Graphium* spp. *Pullularia* spp.
Soybean lung	Soybeans in animal feed	Soybean hull antigens
Wood pulp worker's disease	Contaminated wood pulp	*Alternaria* spp.
Wood dust HP	Contaminated wood dust	*Bacillus subtilis* *Alternaria* spp.
Compost lung	Compost	*Aspergillus* spp. *T. vulgaris*
Cheeseworker's disease	Cheese or cheese casings	*Penicillium* spp.
Wood trimmer's disease	Contaminated wood trimmings, at times in sawmills	*Rhizopus* spp. *Mucor* spp.
Thatched roof disease	Dried grasses and leaves	*Saccharomonospora viridis*
Greenhouse lung	Greenhouse soil	*Aspergillus* spp. *Penicillium* spp. *Cryptostroma corticale*
Coffee worker's lung	Green coffee dust	Unknown
Potato riddler's lung	Moldy hay around potatoes	Thermophilic actinomycetes (*M. faeni*, *T. vulgaris*) *Aspergillus* spp.
Tobacco worker's disease	Mold on tobacco	*Aspergillus* spp.
Wine grower's lung	Mold on grapes	*Botrytis cinerea*
Woodman's disease	Mold on bark and fuel chips	*Penicillium* spp.
Soy sauce brewer's lung	Fermentation starter for soy sauce	*Aspergillus oryzae*
Domestic allergic alveolitis	Decayed wood	Fungi (*Serpula lacrymans*, *Leucogyrophana pinastri*, *Paecilomyces variotii*, *Aspergillus fumigatus*)
Riding school lung	Hay in horse stall	Thermophilic actinomycetes (*M. faeni* [*S. rectivirgula*], *T. vulgaris*)
Stipatosis	Esparto grass (*Stipa tenacissima*), used to make plaster	Esparto grass antigens
Pigeon breeder's disease	Avian droppings, feathers, serum	Altered serum/feather proteins
Turkey handler's disease	Turkey products	Turkey proteins
Chicken breeder's lung	Chicken feathers	Chicken feather proteins
Bird fancier's lung	Domestic and wild bird products	Bird proteins
Duvet lung	Duvet and pillow	Goose proteins
Laboratory worker's HP	Rat fur	Rat urine protein
Pituitary snuff taker's disease	Pituitary powder	Vasopressin
Shell lung	Oyster or mollusk shell	Shell proteins
Miller's lung	Grain weevils in wheat flour	*Sitophilus granarius* proteins
Sericulturist's lung	Silkworm larvae	Silkworm larvae proteins
TDI HP	Toluene diisocyanate	Altered proteins (albumin + others)
MDI HP	Diphenylmethane diisocyanate	
HDI HP	Hexamethylene diisocyanate	
TMA HP	Trimetallic anhydride	Altered proteins

(continued)

TABLE 56-1 Etiologies of Hypersensitivity Pneumonitis *(Continued)*

Disease	Antigen Source	Probable Antigen
Ventilator lung	Contaminated humidifiers, dehumidifiers, air conditioners, heating systems	Thermophilic actinomycetes (*T. candidus*, *T. vulgaris*) *Penicillium* spp. *Cephalosporium* spp. Amoebae *Klebsiella* spp. *Candida* spp.
Basement lung	Contaminated basement (sewage or mold)	*Cephalosporium* spp. *Penicillium* spp.
Sauna taker's disease	Sauna water	*Aureobasidium* spp.
Detergent worker's disease	Detergent enzymes	*Bacillus subtilis*
Japanese summer house HP	House dust, bird droppings (?)	*Trichosporon cutaneum*
Hot-tub lung	Mold on ceiling	*Cladosporium* spp.
Tractor lung	Contaminated tractor, cab air conditioner	*Rhizopus* spp.
Machine operator's lung	Contaminated metal working fluid	*Pseudomonas* spp.
Fertilizer lung	Contaminated fertilizer	*Streptomyces albus*
Sax lung	Saxophone mouthpiece	*Candida albicans*

radiologic findings suggestive of HP; and (3) BAL lymphocytosis. Clinical history remains a key factor in diagnosis. Patients with nonfibrotic disease may present with a history of recent exposure to an inciting agent followed by symptom onset within 4 to 12 h. In contrast, patients with fibrotic HP may not have a clearly defined culprit agent and symptoms are likely more insidious. Thus it may be clinically useful to consider acute and nonfibrotic HP as overlapping in nature (as well as chronic and fibrotic), as long as the prognostic implications of the extent of fibrosis are considered. The identification of the inciting antigen is generally associated with a better prognosis,[18] but the more advanced the fibrosis, the less robust this association becomes.

Identification of antigen exposure can be derived from the clinical history itself. The history should seek to establish a link between a particular exposure (at work, at home, or elsewhere) and previous episodes of "pneumonia." Knowledge of other exposed persons with similar symptoms should be sought. Evidence of repetitive typical symptoms and laboratory and radiologic abnormalities associated with exposure to a particular environment is also highly suggestive of HP. In some instances, a "natural exposure" (i.e., documentation of appropriate symptoms and laboratory abnormalities after intentional exposure to a suspect environmental agent) has been suggested to diagnose HP. A "natural exposure" challenge should not be considered positive unless there is objective evidence of a change in temperature, total peripheral white blood cell count, chest radiograph (or high-resolution CT scan), or a decrease in diffusing capacity of the lungs for carbon monoxide ($\mathrm{DL_{CO}}$) (or arterial $\mathrm{Po_2}$). If the history suggests a relationship between exposure and pulmonary symptoms, evidence of sensitization and the nature of the pulmonary inflammatory response should be interrogated. Sensitization may be indicated by the presence of serum antibody (IgG) to an agent known to be associated with HP, although the sensitivity is generally low. An antigen questionnaire can be used, although no such validated tool has been developed to date. BAL cell counts and differentials lack diagnostic specificity but may helpful in increasing the level of concern for suspected HP; this may be most useful in patients with suspected nonfibrotic HP (in addition to exclusion of infection). Confidence in the diagnosis of HP is enhanced by radiographic imaging suggestive of a "typical HP" pattern (discussed below), a known (presumptive) antigen exposure, and BAL lymphocytosis (although the cutoff levels are uncertain), usually without obtaining histopathologic "confirmation" (which is not always achievable, even with surgical biopsy).

RADIOGRAPHIC FEATURES

The plain chest radiograph may be useful in the initial evaluation of patients with possible nonfibrotic or fibrotic HP (Figs. 56-1 and 56-2), although high-resolution CT chest (HRCT) is the preferred modality for radiographic characterization of presumptive HP (Fig. 56-3). Image acquisition should occur upon deep inspiration, in which all features of lung infiltration may be identified. However, expiratory images are useful in identifying air trapping, an expiratory finding that serves to enhance confidence in diagnosis of nonfibrotic HP, as well as confirmation of heterogeneity of lung attenuation in both forms of the disease. HRCT findings for either fibrotic or nonfibrotic HP are categorized as typical, compatible with, or indeterminate for HP.[19]

The "typical" appearance of nonfibrotic disease is exemplified by a combination of features indicative of parenchymal infiltration (such as ground glass opacification [GGO] and mosaic attenuation), as well as features of small airways disease (ill-defined centrilobular nodules and air trapping on expiration) diffusely distributed, with or without basal sparing. Mosaic attenuation on inspiratory imaging reflects the coexistence of hyperattenuated (from inflammatory infiltration) and mildly hypoattenuated regions (hypoperfusion due to bronchiolar obstruction). Features considered "compatible" with nonfibrotic HP include uniform GGO, airspace consolidation, the presence of cysts, and variant distribution (basal or peribronchovascular predominance).

The "typical" appearance of fibrotic HP is a combination of interstitial fibrosis (coarse reticulation with minimal architectural distortion/honeycombing) along with clear evidence of small airways disease (ill-defined nodules, mosaic attenuation, air trapping), notably exemplified by the "three-density sign" (Fig. 56-4). Patterns "compatible" with fibrotic HP include a UIP pattern of fibrosis, along with subtle features of small airways disease, or extensive GGO with

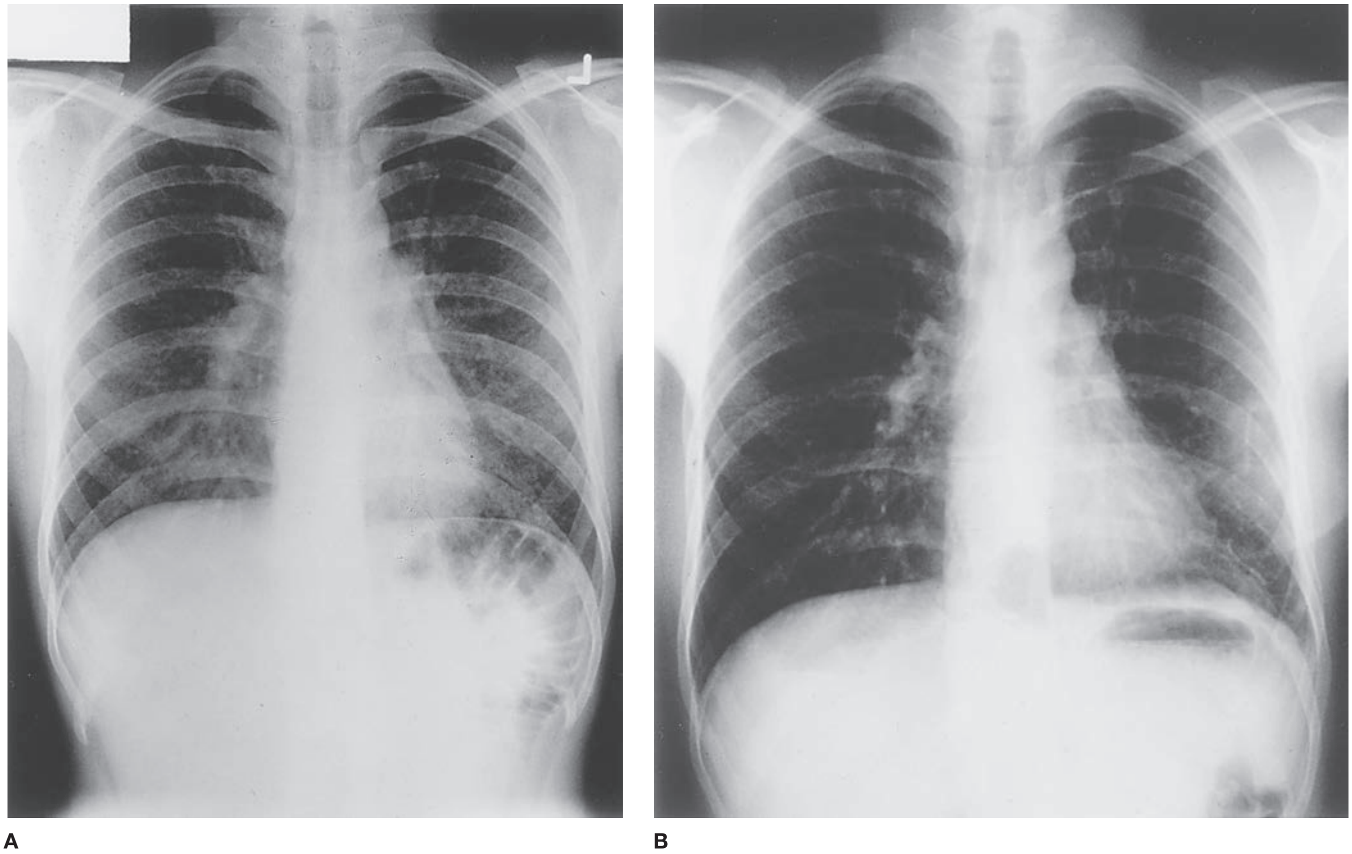

Figure 56-1 **A.** Chest radiograph of a patient with pigeon breeder's disease with fever, dyspnea, and bibasilar rales. The patient had kept pigeons for 5 years and presented with fever, dyspnea, and myalgias approximately 8 h after cleaning the pigeon coop. He had serum antibody to pigeon dropping extract. Note bilateral lower lobe 2- to 3-mm nodules. **B.** Chest radiograph of the same patient 2 weeks later without specific treatment. Note clearing of the lower-lobe nodules (and the staples in the left chest from a surgical lung biopsy).

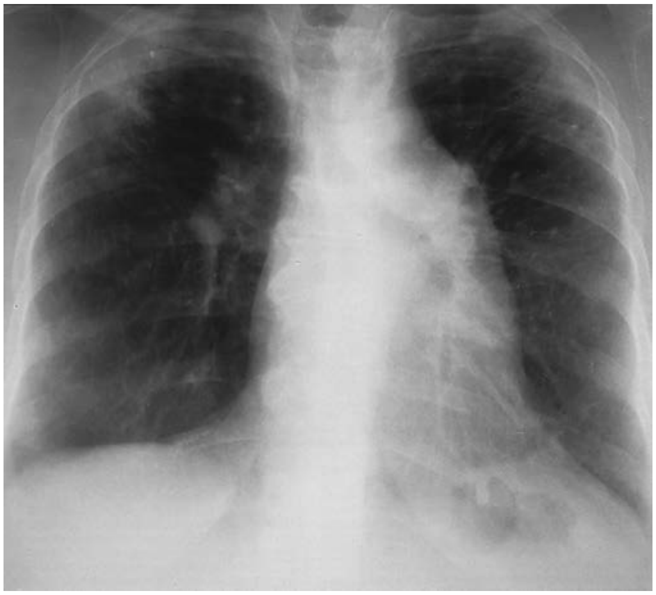

Figure 56-2 Chest radiograph of a patient with bird fancier's disease who presented with progressive dyspnea and weight loss. She had kept 2 to 3 parakeets in her home for 15 years and did not notice episodic fever or acute dyspnea. She had positive serum precipitins to parakeet serum, restrictive physiology, and exertional hypoxemia. Note the diffuse radiodensities, loss of volume of the upper lobes, and signs of pulmonary hypertension.

subtle features of fibrosis or small airways disease. "Indeterminate" patterns include a UIP or fibrotic nonspecific interstitial pneumonia (NSIP) pattern, organizing pneumonia–like pattern, and absence of features of small airways disease.[19] Highly suggestive of fibrotic HP, the three-density pattern indicates a mixed infiltrative and obstructive disease, involving sharply separated regions of three attenuations: areas of normal lung, infiltrative GGO, and patches of hyperlucent lung, or preserved lobules and low-density lobules within the same lobe.[15] Although highly specific for fibrotic HP, the three-density sign is present in a minority of cases.[22] At the same time, any pattern of interstitial lung disease that does not include evidence of small airways involvement is indeterminate for fibrotic HP,[17] although in the appropriate clinical context it may be adequate for a provisional diagnosis.

LABORATORY FINDINGS

Patients with HP often have a peripheral blood leukocytosis with neutrophilia and without eosinophilia. As mentioned above, prominent cellular abnormalities may also be seen in the BAL fluid, which may provide support for the diagnosis. At time points greater than 5 days after the last exposure, BAL fluid lymphocytosis (typically 30% to 70% of total cells) may be noted, in both nonfibrotic and fibrotic HP. This may also be helpful in distinguishing HP from idiopathic pulmonary fibrosis (IPF) and sarcoidosis, although it has been challenging to determine a threshold of BAL lymphocytosis that can distinguish HP from other ILDs with high sensitivity and specificity. However, a consensus threshold of 30% is thought to be reasonable in the absence of high-quality experimental data.[23]

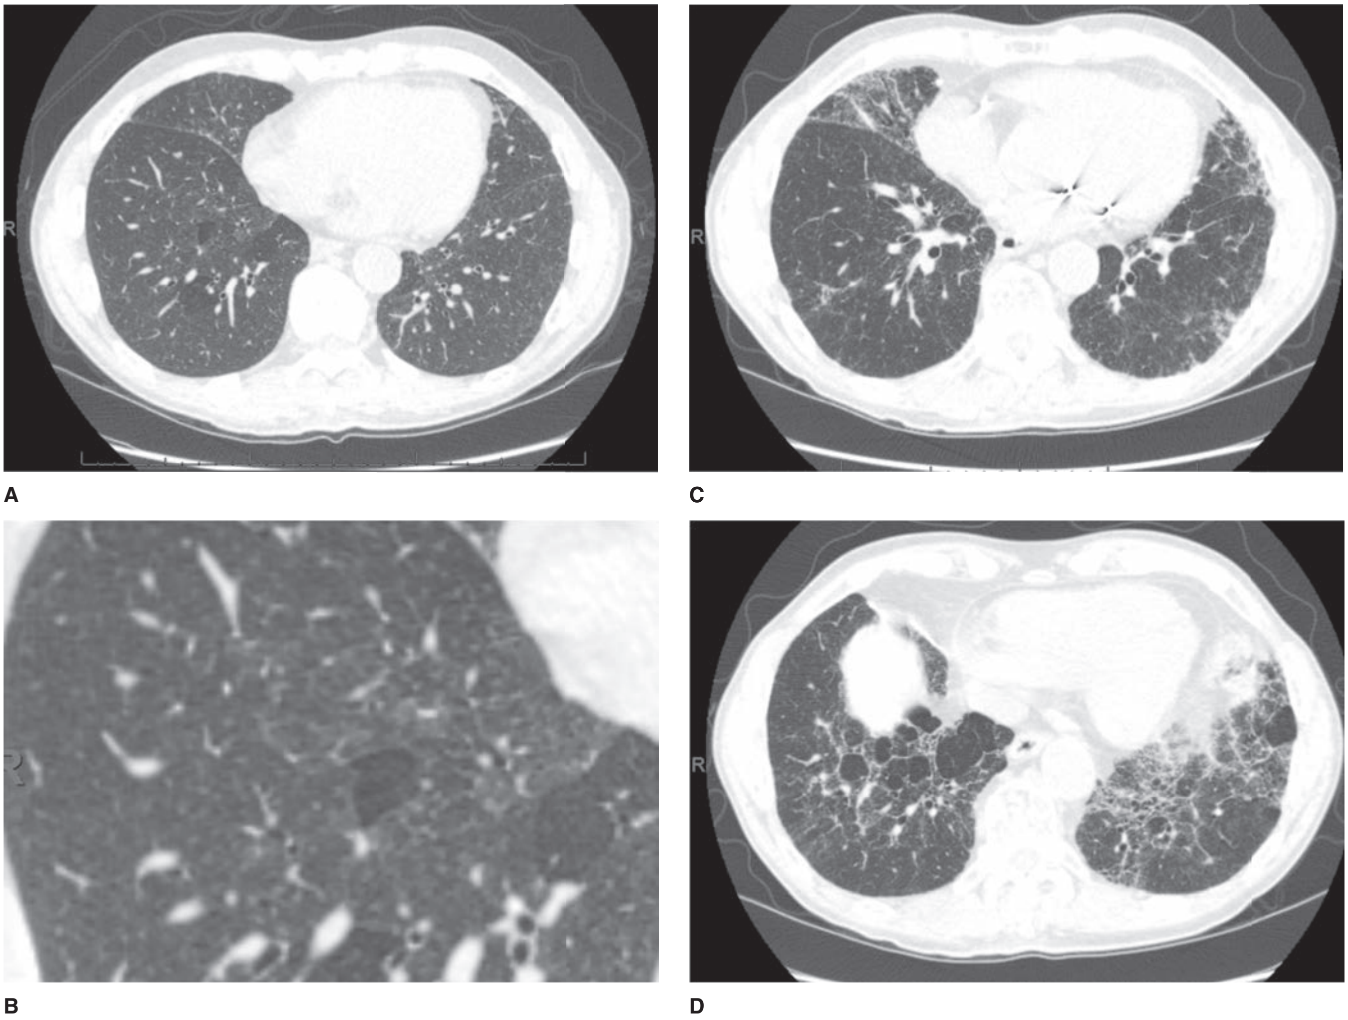

Figure 56-3 High-resolution CT scan of a nonsmoking patient without a clear exposure history who presented initially with dyspnea on exertion and a mild restrictive ventilatory defect. Bronchoalveolar lavage revealed significant lymphocytosis, and he was started on corticosteroid therapy with considerable improvement. As shown in the top left panel, there is diffuse abnormality of the lung parenchyma with patchy centrilobular nodularity and mosaic attenuation, which are quite diffuse in the craniocaudal and axial planes *(magnified image of right anterior region shown in bottom left panel)*. He was lost to follow-up, then returned 5 years later with worsening dyspnea and exertional hypoxemia. Repeat CT *(right panels)* showed continued evidence of centrilobular nodularity and mosaic attenuation, with moderately extensive reticular abnormalities, patchy ground glass, and traction bronchiectasis. The fibrotic abnormalities show a lower lung predominance. These imaging findings are highly suggestive of fibrotic hypersensitivity pneumonitis, with evolution from a nonfibrotic pattern initially, with moderate progression of fibrosis over the 5-year interval.

In most instances of HP, BAL fluid lymphocytes are virtually all $CD3^+$ (T lymphocytes), with a relative increase of $CD8^+$ cells, such that the CD4:CD8 ratio is usually less than 1 (normally 2–2.5, as in peripheral blood). The utility of BAL lymphocytosis in fibrotic HP is highly variable, although in the "proper clinical context" high BAL lymphocyte counts may increase the probability of HP.[24]

Many patients with HP have easily demonstrable serum antibodies (typically IgG, IgM, and IgA) to the offending material detectable by a variety of methods. Since antigen preparations are not standardized, it is difficult to be confident of the meaning of a negative result. Furthermore, since serum antibody is also present in many exposed, but not ill, subjects at similar levels as patients with HP, the presence of antibody should be considered supporting data in the proper clinical context. In asymptomatic pigeon breeders, the prevalence of antibody to pigeon antigens may be as high as 87%.[25] In a study of more than 3000 Finnish farmers, the prevalence of anti–*Micropolyspora faeni* serum antibody may be up to 8.6%.[26] The occurrence of serum antibody is not consistently related to apparent exposure (i.e., hours of exposure or intensity of exposure) in most instances of HP. In addition, serum antibody has been reported to wane after cessation of exposure, so patients with chronic presentations of HP who have not been exposed for some time may not have demonstrable antibody. In farmer's lung disease, approximately 50% of patients with initially positive serum antibody to *M. faeni* (*Saccharopolyspora rectivirgula*) lose demonstrable antibody 6 years after cessation of exposure, although a significant proportion of those who continue to farm may also lose detectable antibody in more than 5 years.[27] Therefore, it is possible that patients with HP will have no detectable serum antibody owing to the assays themselves or the waning of antibody over time.

Nonspecific markers of inflammation, such as increased erythrocyte sedimentation rate and C-reactive protein, are often elevated during an acute episode of HP, but they are quite nonspecific. In contrast to sarcoidosis, the serum angiotensin-converting enzyme levels are not elevated. Skin tests (either immediate or delayed type) to detect sensitization to the suspected antigens are not useful.

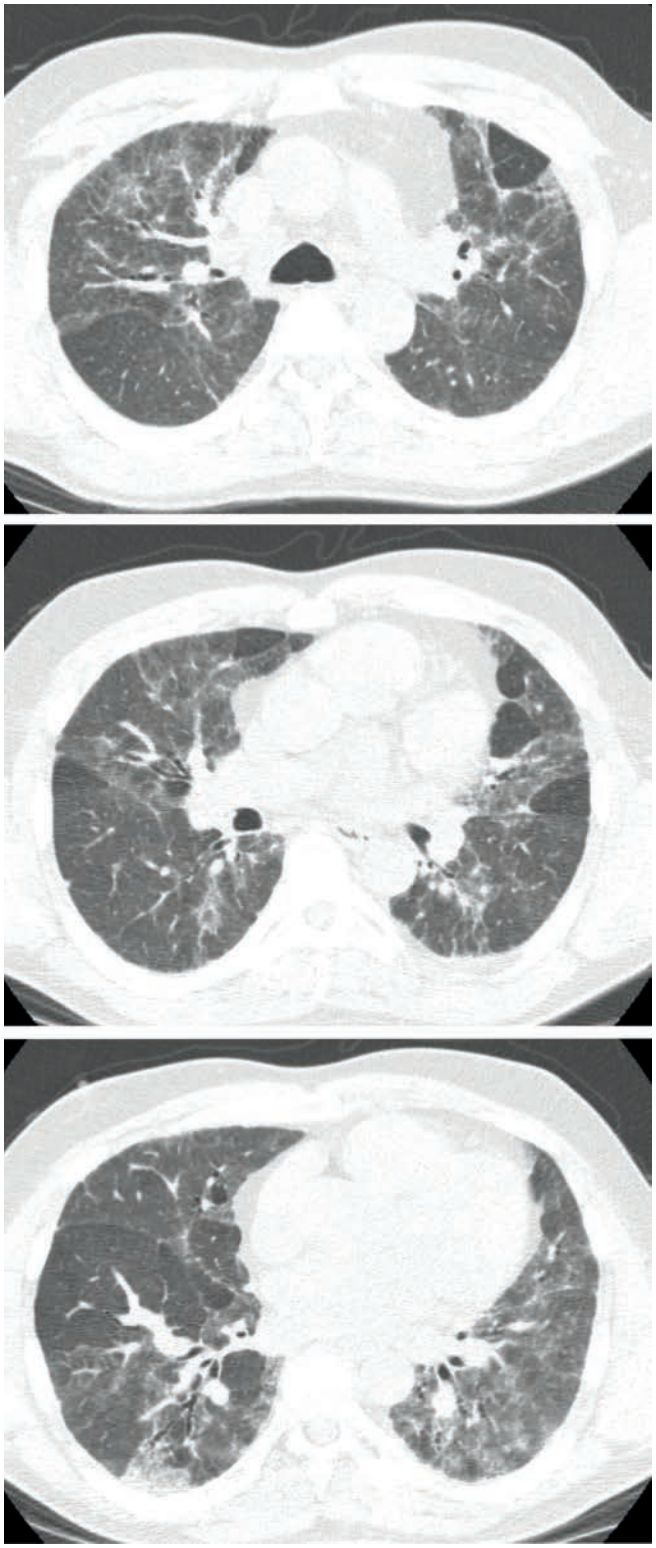

Figure 56-4 "Three-density pattern" on high-resolution CT scan strongly suggestive of fibrotic HP, in a patient (whose avocation was woodworking) with progressive dyspnea, hypoxemia, and restriction, despite empiric avoidance of wood/wood dust, and treatment with corticosteroids and mycophenolate. In each of these inspiratory images there is evidence of ground glass opacification, mosaic attenuation with zones of diminished attenuation/hypoperfusion, and areas of normal-appearing parenchyma. There is also evidence of modest reticular/fibrotic abnormalities and traction bronchiectasis.

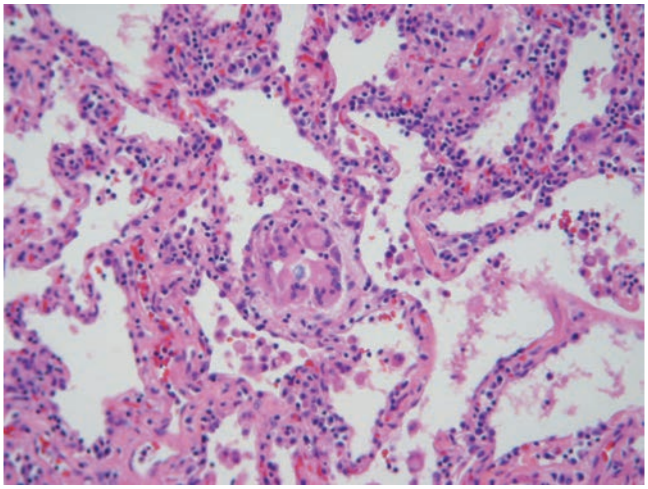

Figure 56-5 Low-power view (20×) of H&E-stained section of surgical lung biopsy from a patient with bird fancier's disease. There is nonspecific interstitial mononuclear inflammation and loosely formed granulomatous lesions.

Pulmonary function tests may be restrictive, obstructive, or mixed. There is increased lung elastic recoil, and usually decreased $\mathrm{DL_{CO}}$. Arterial hypoxemia with hypocapnia, reflecting an increased A–a oxygen gradient, either at rest or after exercise is common. However, 39 of 177 patients (22%) with $\mathrm{DL_{CO}}$ data available to the HP Study Group[14] displayed normal diffusion, defined as a $\mathrm{DL_{CO}} \geq 80\%$ predicted at the time of diagnosis. Many patients with HP (20% to 40%) also exhibit increased nonspecific airway reactivity, and 5% to 10% may develop clinical asthma.[28]

HISTOPATHOLOGY

A lung biopsy specimen may be required when there is significant doubt about the diagnosis, or when the risk of treatment based upon a provisional diagnosis outweighs the risk of the biopsy. Transbronchial lung biopsies usually do not provide sufficient material to fully establish the presence and interrelationships of granulomas, bronchiolitis, and interstitial inflammation, so surgical lung biopsies may be necessary. These often reveal chronic interstitial and alveolar inflammation with infiltration of plasma cells, mast cells, macrophages, and lymphocytes, usually with poorly formed nonnecrotizing granulomas (Figs. 56-5 and 56-6).

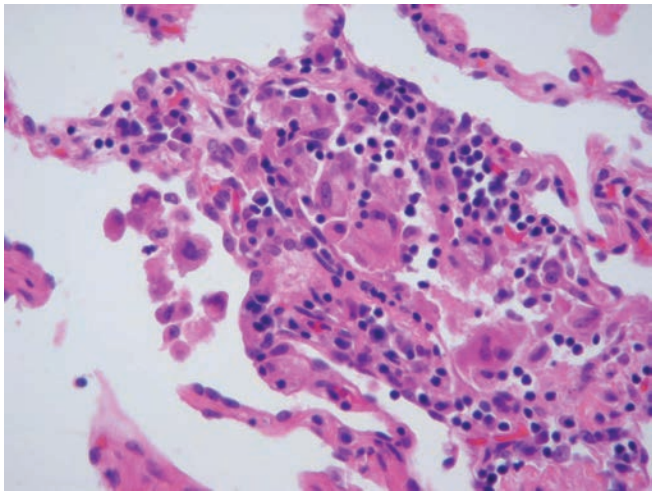

Figure 56-6 Higher-power view (40×) of the section shown in Fig. 56-5.

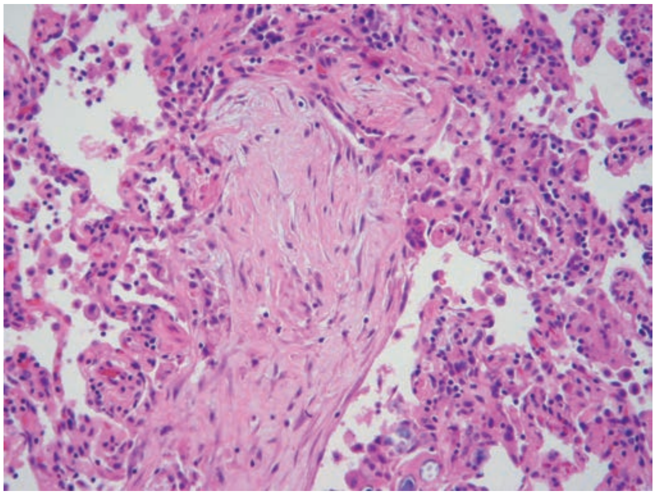

Figure 56-7 Organizing pneumonia in a patient in a patient with bird fancier's disease.

The inflammation usually extends from the terminal bronchioles into the parenchyma. Foamy macrophages are usually evident in the alveoli. There is often bronchiolitis, as well as occasional bronchiolitis obliterans. Organizing pneumonia may be present in up to half of patients with HP (Fig. 56-7). Conversely, patients with recognized cryptogenic organizing pneumonia (COP) may have underlying HP, whether or not other histologic manifestations are evident. Varying degrees of interstitial fibrosis also are often present. The granulomatous interstitial inflammatory responses of HP and sarcoidosis can be difficult to differentiate, but in HP granulomas are usually smaller, poorly differentiated, and loosely arranged and contain more lymphocytes and fewer multinucleated giant cells. The granulomas of HP also tend to occur adjacent to bronchioles, and not in subpleural regions. In the absence of granulomas, the pattern may resemble that of nonspecific interstitial pneumonitis, although the bronchiolocentric nature of the lesions and the presence of giant cells, organizing pneumonia, or bronchiolar metaplasia may be clues suggesting underlying HP.

The histopathologic findings that provide high confidence in the diagnosis of "typical" nonfibrotic (cellular) HP are bronchiolocentric cellular (lymphocytic) interstitial pneumonia, cellular bronchiolitis (particularly with organizing pneumonia and foamy alveolar macrophages), and poorly formed nonnecrotizing granulomas (particularly in peribronchial interstitial regions). Furthermore, there should be no evidence of signs of an alternative diagnosis, such as extensive lymphoid hyperplasia or well-formed and/or necrotizing granulomas. A diagnosis of "probable" nonfibrotic HP can be based upon the same features of "typical" nonfibrotic HP described previously, in the absence of nonnecrotizing granulomas. Histologic evidence of cellular NSIP, organizing pneumonia, or peribronchiolar metaplasia is "indeterminate" for nonfibrotic HP.[19]

Histopathologic findings for a high-confidence diagnosis of "typical" fibrotic HP include chronic fibrosing interstitial pneumonia with a fibrosing NSIP pattern, airway-centered fibrosis, and peribronchiolar metaplasia, with evidence of poorly formed nonnecrotizing granulomas, with or without cellular bronchiolitis or organizing pneumonia (and no evidence of an alternative diagnosis; Fig. 56-8). A diagnosis of "probable" fibrotic HP may be made with similar findings, in the absence of poorly formed granulomas. A biopsy that is "indeterminate" for HP may have chronic fibrosing interstitial pneumonia or a fibrotic NSIP pattern, with or without organizing pneumonia or cellular bronchiolitis.[19]

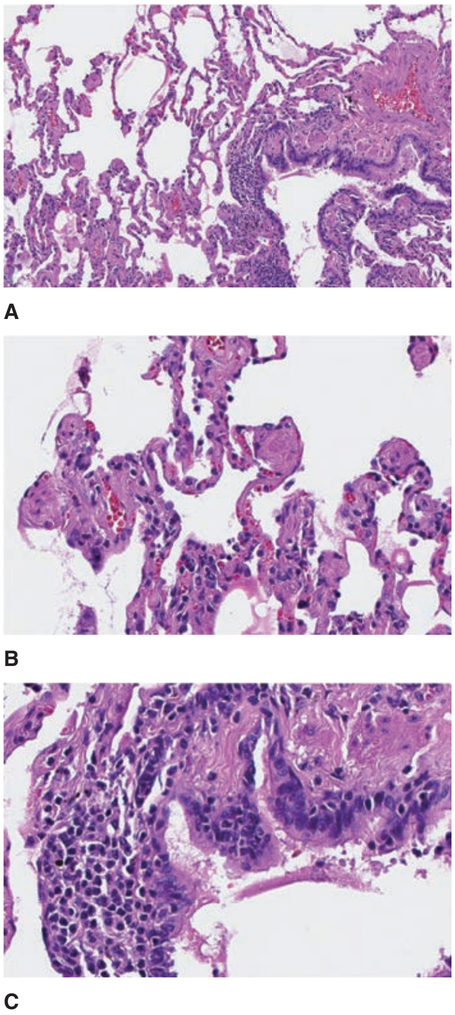

Figure 56-8 Histopathologic evidence of fibrotic HP, exemplified by a patchy, predominantly airway-centered inflammatory and fibrosing process. **A.** Low-power view of mild cellular bronchiolitis and peribronchial interstitial inflammation, with focal lymphoid aggregates and fibrosis. **B.** Higher-power view of interstitial pneumonitis with fibrosis and occasional fibroblastic foci. **C.** Peribronchial metaplasia, focal lymphoid aggregates, and fibrosis.

IMMUNOPATHOGENESIS

An important feature of HP is the great variability of susceptibility among exposed populations and the apparent resistance to illness of most exposed persons. Possible reasons include differences in the nature of the exposure, or differences in the host response to exposure, which may be inborn and/or acquired. There have been numerous reported correlations between HP and specific HLA class I and class II haplotypes.[29–32] Similar correlations have been reported between polymorphisms in the coding region of tumor necrosis factor alpha (TNF-α)[31] as well as its promoter.[33] Similarly, polymorphisms in the promoter of TIMP-3,[34,35] responsible for regulation of TNF-α processing, appear to correlate with HP disease susceptibility. Notably, a MUC5B promoter variant, described as an important risk factor for IPF, also has been associated with an increased risk of fibrotic HP.[36,37] Interestingly, a variety of polymorphisms in the telomerase complex, initially linked to familial forms of IPF, also are associated with increasing susceptibility to fibrotic HP.[37,38] These findings may suggest a genetic predisposition to progressive fibrosis, irrespective of the underlying disease, and the frequency of family history of IPF in patients with fibrotic HP suggests possible host susceptibility to progressive fibrosing manifestations of multiple types of insult to the lung.[39]

HP is seen worldwide, and the most commonly implicated antigens are thermophilic actinomycete species, fungi, and bird proteins. Thermophilic actinomycetes (e.g., *Saccharopolyspora rectivirgula*) and a variety of fungi (e.g., *Aspergillus* species and *Penicillium* species) are implicated in HP in a variety of occupations, such as farming, but may also be responsible for the disease acquired in home and work environments. A complex mixture of high- and low-molecular-weight proteins from avian serum, feces, and feathers produce the "bird fancier's lung," and it is the complexity of such antigenic mixtures that may underlie the unique immunopathologic manifestations dominated by T cell–mediated effector activites.[36,40,41] It is reasonable to assume that the normal immune responses to infectious diseases are subverted in a disease state such as HP—and thus the panoply of host responses, including innate and adaptive mechanisms, are likely activated simultaneously by inciting exposures.

There is ample evidence that the complex mixtures of antigens contain ligands for innate Toll-like receptors (TLRs), which are a family of cellular receptors that respond to pathogen-associated molecular patterns (PAMPs) common to a multitude of infectious microorganisms. This results in rapid inflammatory activation necessary for initiating a robust immune response.[42] The role of TLRs in the generation of HP is incompletely defined, but it is known, for example, that fungal cell wall components (such as beta-glucans) activate TLR2 and may be aerosolized from moldy materials, such as in mold-damaged buildings.[43] Similarly, TLR9 may be of particular importance, as it may be triggered by fungal DNA,[44] and like all the TLRs, it activates interferon α/β (IFN-α/β) responses critical in dendritic cell antigen uptake, migration to regional lymph nodes, and sensitization of CD8$^+$ T cells through cross-presentation of phagosomal antigens via class I MHC. IFN-α/β–induced cross-presentation of particulate antigens by alveolar and bronchiolar epithelial cells may also make them targets of CD8$^+$ T cell recognition.[45]

By the time the disease is clinically evident, lung tissue gene expression profiles indicate ongoing T cell–driven inflammation (in contrast to the profiles of IPF and NSIP[46]). The T cell responses evident in HP are notable for the predominance of CD8$^+$ cells and the expression of IFN-γ, the prototypic cytokine of type 1 (Th1/Tc1) inflammatory processes. Expression of IFN-γ–dependent chemokines, such as CXCL9 and CXCL10, is also observed in HP lungs, which likely serves to amplify the type 1 (Th1/Tc1) inflammation. Not unexpectedly, CD8$^+$ T cells in BAL of HP patients strongly express CXCR3, the receptor for both of these chemokines.[40] CD8$^+$ T cells isolated from patients with presumptive nonfibrotic/acute HP demonstrate oligoclonality, the characteristic result of (competitive) antigen-driven proliferation.[41] Secondary recruitment of inflammatory macrophages, and the cytokines produced by them, likely augment the inflammatory milieu.[47] TNF-α, produced by activated macrophages (as well as by CD8$^+$ T cells), likely participates both in the amplification of the inflammation and the activation/degranulation of neutrophils that may be recruited to the alveolar space.[47,48]

There is a curious predominance of nonsmokers in patients with nonfibrotic HP,[49] possibly due to the anti-inflammatory effects of nicotine.[50] Activation of nicotinic acetylcholine receptor alpha-7 has been shown to suppress not only proinflammatory cytokine production by innate immune cells such as macrophages but also reactivity of CD4$^+$ T helper cells.[50–52] However, consistent with observations in other fibrosing ILDs, long-term smoking is associated with increasing fibrosis.[53,54]

PROGNOSIS AND TREATMENT

Prognosis varies considerably with the type of HP and even the geographic location. For example, farmer's lung disease has a good prognosis in Quebec, even in farmers who continue to farm. However, farmer's lung disease in Finland often results in significant physiologic impairment and even death. Pigeon breeder's disease has a good prognosis in the United States and Europe, whereas the same disease in Mexico has a 30% 5-year mortality.[55] The reasons for these differences are not clear but may include differences in the nature of the antigen and the exposure.

Identification of the offending antigen is critical to effective avoidance, which is the primary intervention in all forms of HP. This is often not possible nor practical when the exposure is occupational, such as in farmer's lung disease. In addition, most farmers who continue to be exposed may fare no worse than those who leave their farms.[56] Nevertheless, removal from exposure to the offending antigen(s) is often sufficient to resolve symptoms and physiologic abnormalities in nonfibrotic HP. Measures to reduce antigenic burden may include protective equipment and reducing microbial contamination of the home or work environment. Elimination of excess moisture, reduction in humidity, repair of water-damaged materials, and regular cleaning of humidifiers, ventilation, and air conditioning equipment all contribute to reduction in mold and other microbial colonization that may predispose to sensitization. Removal of birds from the home of patients with bird-fancier's disease is a critical aspect of treatment, but antigens may persist for extended periods despite thorough cleaning of the home environment.[57]

Systemic glucocorticosteroids are usually required to treat severely symptomatic patients, although there is no formal evidence that such treatment is associated with long-term abatement of symptoms or radiologic or pulmonary function test abnormalities.[27,58] The usual treatment is with corticosteroids, such as prednisolone 40 to 60 mg per day for several weeks, followed by a gradually tapering dose over 1 to 2 months. Patients with farmer's lung disease treated with prednisolone, compared with those not treated, demonstrated slightly more rapid resolution of some radiologic abnormalities (GGO) and physiologic impairment (slight improvement of $D\textsc{l}_{CO}$, no difference in lung volumes or arterial $P\textsc{o}_2$). However, there were no differences between the groups 6 months after the diagnosis of HP. The management of chronic fibrotic HP is more challenging, as longer-term therapy may be necessary and steroid toxicity is limiting. Steroid-sparing agents (mycophenolate mofetil or azathioprine), which may be administered for more extended time periods with considerably less toxicity, have shown promise in several retrospective studies with improvements in $D\textsc{l}_{CO}$, although their utility has not been examined prospectively.[59] Antifibrotic agents have proved effective in slowing functional decline and disease progression in IPF, and a recent trial showed similar benefit for the use of nintedanib in progressive, non-IPF fibrosing ILD, including chronic fibrotic HP.[60,61] Finally, lung transplantation is an option for some patients with end-stage fibrotic HP; survival at 1, 3, and 5 years is better than after transplant for IPF.[62] Of note, in one study, 2 of 31 transplanted HP patients had recurrence of their disease despite immunosuppression, both of whom had moved back into their prior residence.[16]

Among patients with chronic/fibrotic HP, the inability to identify an inciting agent was independently associated with shortened survival.[63] Even when an inciting agent is identified, many patients with chronic HP present with advanced fibrosis and physiologic abnormalities that are only partly reversible after cessation of exposure. At the same time, progression of disease has been observed even after complete exposure avoidance,[64] suggesting the possibility of self-perpetuation in some cases. The specific nature of the radiographic and histopathologic findings in these patients at the time of diagnosis, particularly the extent of the fibrosis, may help predict subsequent clinical course of the disease.[65,66] In addition, patients with advanced fibrotic HP may be prone to acute exacerbations, not unlike those observed in IPF patients.[67,68]

In conclusion, HP is an immunologically mediated lung disease likely mediated primarily by T cell responses to inhaled antigens. The diagnosis requires careful history, appropriate laboratory tests, and lung biopsy in selected cases. In nonfibrotic HP, avoidance of exposure is usually associated with a good prognosis; corticosteroids are indicated in severely symptomatic patients. Steroid-sparing agents as well as antifibrotic drugs may be indicated in chronic fibrotic HP. Because of constantly changing environmental exposures, new examples of HP are continually being described, representing an ongoing challenge in patients presenting with undefined chronic interstitial lung disease.

CHAPTER 57

Radiation Pneumonitis

James H. Laird
Kenneth B. Roberts
Roy H. Decker
Henry S. Park

INTRODUCTION

The discovery of x-rays by Roentgen in 1895 and of radium by the Curies in 1898 revolutionized medicine at the turn of the 20th century.[1–3] Roentgen's first paper on x-rays illustrated the power of diagnostic imaging with a remarkably detailed radiographic image of Frau Roentgen's hand. As researchers around the world built vacuum tubes and acquired radioactive sources for their studies, it rapidly became apparent that these invisible radiations could produce dangerous, and even lethal, injuries.[1–3] Erythema, chronic dermatitis, ulceration, loss of hair, and eye injuries were soon reported in patients who received large doses of radiation during prolonged fluoroscopy procedures, and further toxicities were observed in physicians, technicians, and scientists exposed to unshielded radiation sources. The development of these radiation injuries suggested that radiation might be useful in the treatment of cancer; indeed, patients with cancer were treated with radiation therapy as early as 1896.[1–3] Radiation was found to inhibit the growth of tumors, but this benefit came with the cost of injury to normal tissues within the irradiated areas. The relative sensitivity of the lung to injury from radiation became apparent early in the development of radiation oncology. The clinical syndromes of dyspnea, cough, fever, and radiographic infiltrates occurring weeks to months after irradiation of the thorax were dramatic enough to be described as early as 1922.[4]

For clinicians interested in pulmonary medicine, understanding radiation pneumonitis is important. Because the chemical mediators of radiation effects, both beneficial and harmful, are free radicals, understanding the pathway leading to radiation injury in the lung can be useful in elucidating mechanisms of other lung injuries.[5,6] In addition, understanding radiation pneumonitis has practical value to physicians in many areas of medicine. Nearly 40% of men and women in the United States will be diagnosed with cancer at some point in their lifetimes, and the majority of these patients will be permanently cured of their malignancies.[7] Approximately 60% of all patients with cancer receive radiotherapy at some point in the treatment of their malignancies, and radiotherapy will remain an important component of cancer treatment for the foreseeable future. Because of this, every physician can expect to care for many patients who are receiving radiotherapy or have received radiotherapy at some point in the past.

In addition to an association with acute or subacute pulmonary disease, radiation can lead to chronic toxicities. For instance, respiratory diseases are known to be a cause of increased late morbidity and mortality in the survivors of the atomic bombs in Hiroshima and Nagasaki.[8] Additionally, studies of plutonium workers have shown an excess incidence of pulmonary fibrosis, demonstrating lung injury may be produced by inhalation of insoluble particulate radionuclides that are deposited in lung tissue and produce long-term irradiation of the tissue.[9] Radiation injury to lung can occur not only through radiotherapy but also through exposure from occupations, accidents, or acts of war or terrorism.[6] An understanding of the potential toxicities of radiotherapy and other exposures to radiation, including radiation pneumonitis, can be critical to patient care.

Many neoplasms involving the thorax are treated with regimens that include the use of radiotherapy to produce either cure or palliation. Radiotherapy is principally a localized, anatomically based modality. The success of radiotherapy hinges on delivering radiation selectively to the sites of malignant disease while sparing, to the maximal extent possible, the uninvolved normal tissues.[1,10] To plan radiotherapy treatments effectively, the radiation oncologist must have a sophisticated appreciation of the malignancy being treated and understand its biologic behavior, patterns of local and metastatic spread, radiosensitivity, and factors that influence the responses of individual patients to therapy. The radiation oncologist must also consider the effects of radiation on normal tissues within the treatment volumes.

Multiple factors, including radiation dose, fractionation pattern, volume of the tumor and involved margins, prior or planned use of other therapies such as surgery or systemic chemotherapy, and presence of other diseases influence the probability of both controlling the neoplasm and producing toxic reactions. For cancers of the lung, esophagus, pleura, mediastinum, breast, and chest wall, as well as for lymphomas involving the thorax, optimal treatment frequently involves use of multiple overlapping x-ray beams (or possibly proton or electron beams) planned to encompass the tissue at risk of containing cancer. Although treatments are carefully planned to minimize exposure to healthy normal tissue, some normal tissue will necessarily be included in the radiation fields. The radiation sensitivity of the specific tissues in the irradiated fields and the acceptable level of risk for complications combine to limit the dose of radiation that can be administered. The planning of radiotherapy always involves a balance of benefit and risk; the probability of controlling the malignancy increases with increasing radiation dose, but so does the probability and severity of the potential complications.

To illustrate the mechanisms involved in planning radiotherapy treatments, a treatment plan is depicted in Fig. 57-1A. The two images displayed represent axial slices of the dose distribution for treatment of a patient with stage IIA non–small-cell lung cancer who was not a surgical candidate. Treatment was to 60 Gy in 30 fractions, and a color-wash display in which the highest radiation dose is shown in red and lower doses in shades of blue is shown for doses above 20 Gy. This represents the sum of multiple rotating arcs of radiation using intensity-modulated radiation therapy (IMRT), in which computer-based planning is used to deliver a high dose to the tumor target with specific dose limits to normal tissue structures.

In Fig. 57-1B, CT scans obtained 6 weeks post-radiotherapy demonstrate radiation-induced inflammatory changes. The changes roughly correspond to the high dose region of radiotherapy, though not precisely; the approximate correlation with the high-dose radiotherapy region is typical for IMRT plans. In this case, the patient also reported mild exertional shortness of breath and nonproductive cough, not significantly limiting her functionality. The radiation dose delivered to the lung tissue is shown in a cumulative dose–volume histogram, in Fig. 57-1C, which integrates the percentage of the volume of the organ at risk (on the vertical axis) receiving the specified cumulative radiation dose (on the horizontal axis). While this is a simplified representation of a complex dose–volume relationship, this concept has become important in analyzing radiation dose delivery and correlating dosimetry with treatment outcome. In the illustration, the volume of lung receiving greater than or equal to 20 Gy (V_{20}) is 27%, which corresponds with an under 20% risk of symptomatic radiation pneumonitis.

Figure 57-1 An 89-year-old woman with stage IIA non–small-cell lung cancer was treated with radiotherapy and concurrent carboplatin and paclitaxel. **A.** Two representative axial slices of the dose distribution from a volumetric arc therapy (VMAT) plan are overlaid on a treatment-planning CT scan. Using a color-wash format, radiation dose is demonstrated from 20 Gy *(green)* to 64 Gy *(red)*. The volume intended to be treated with full dose radiotherapy (planning treatment volume) is outlined in green. **B.** Six weeks after completion of treatment, the patient developed a mild dyspnea and nonproductive cough. On CT chest, she was found to have a new multifocal consolidation near the area of treatment and within the lower-dose region (20 Gy) of radiation therapy. **C.** Cumulative dose–volume histogram of the entire treatment course for bilateral lung tissue. The volume of normal lung receiving 20 Gy or more (V_{20}) is 27%.

Radiation changes also frequently are present after high-dose focal radiation treatments such as stereotactic body radiation therapy (SBRT). Figure 57-2A displays in color-wash a radiation treatment plan for a patient with metastatic colorectal cancer and isolated progression in a left upper lobe lung metastasis. She was treated to a prescribed dose of 54 Gy in 3 fractions. Figure 57-2B demonstrates radiation changes in the left lung 6 months after treatment, which similarly correlate with the areas receiving a higher dose of radiotherapy.

In the cases presented, if the malignancy is cured, or the patient experiences the desired improvement in symptoms with tolerable toxicity from the radiotherapy, the treatment would be considered a success even if accompanied by radiographic changes or by other subclinical damage to the lung or other organs. Symptomatic

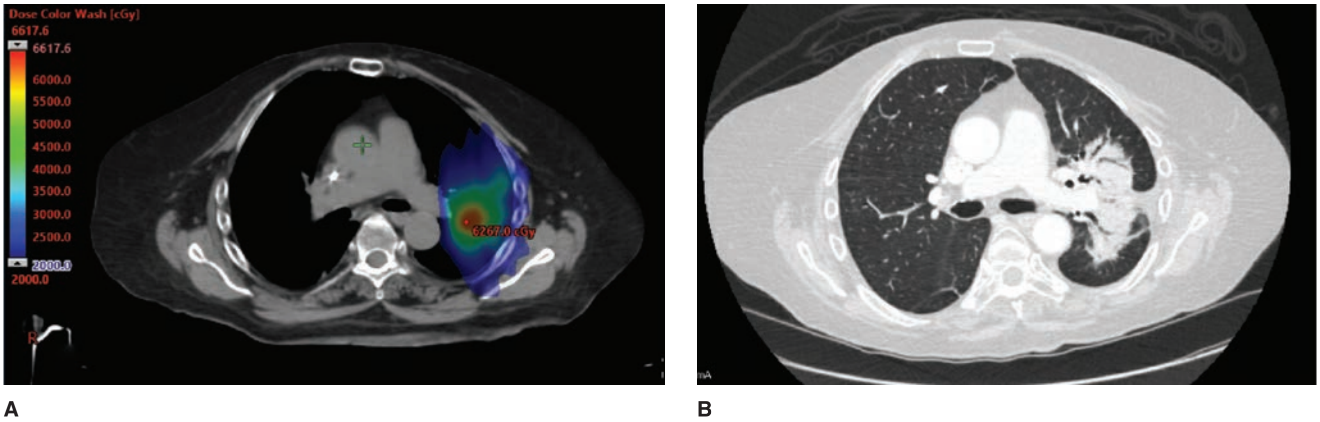

Figure 57-2 A 76-year-old woman with stage IV colon adenocarcinoma initially diagnosed 10 years earlier presented with a progressive left upper lobe lung metastasis, which was her only active site of disease after prior chemotherapy. She underwent SBRT to 54 Gy in 3 fractions. **A.** A dose color-wash overlay of her treatment plan is shown, with doses from 20 Gy to a maximum of 66 Gy. **B.** Six months after completing radiotherapy, she was noted to have a consolidation in the area of prior treatment with adjacent pleural thickening but no new respiratory symptoms, consistent with grade 1 pneumonitis.

pulmonary toxicity is, however, a potential consequence of thoracic radiotherapy that sometimes overshadows the benefits of treatment.

BRIEF OVERVIEW OF RADIOLOGIC PHYSICS

External beam radiotherapy is most commonly delivered using x-rays or gamma rays. Both of these radiations are high-energy electromagnetic waves or photons that are able to cause ionizations when interacting with matter.[11] The only difference between them lies in the manner in which they are produced: gamma-ray photons are emitted from atomic nuclei during the decay of radioactive atoms, and x-rays are produced when high-energy electrons strike a target material and interact with the electron shells of atoms in that target, causing them to emit x-ray photons (the *bremsstrahlung effect*). After its emission, an individual x-ray photon is indistinguishable from a gamma-ray photon. Thus, although the discussion below uses x-rays as examples, the principles are equally applicable to radiotherapy using high-energy gamma rays (e.g., from cobalt-60 teletherapy units or brachytherapy using implanted radioactive sources).

The x-rays used for diagnostic imaging are in a relatively low-energy range, in which the dominant interaction of photons with matter is through the "*photoelectric effect*." In this process, absorption of a photon causes an electron to be ejected from the inner shell of an atom. The probability of photoelectric interactions increases as a function of the cube of the atomic number, that is, as Z3. Consequently, large, heavy atoms absorb low-energy diagnostic x-rays much more efficiently than smaller, lighter atoms.

Diagnostic radiology capitalizes on the large differences between the absorption of low-energy x-rays in materials with different compositions, for example, air, soft tissue (which is 70% water and, therefore, composed primarily of the small atoms hydrogen and oxygen), bone (with its high calcium content), and administered contrast agents containing barium, iodine, or other heavy atoms. The differences in absorption are used to image anatomic structures. In contrast, high-energy x-rays used in radiotherapy interact with matter primarily by a phenomenon called the "*Compton effect*," in which x-rays cause ionization of atoms via interactions with their outer electron shells. The Compton effect is not dependent on the atomic number, but is, instead, a function of the electron density. Because the electron densities of most biologic tissues are relatively uniform, for the purposes of most radiotherapy dosimetry, it is reasonable to assume that a patient is of uniform density, equivalent to water.

An important caveat to radiation dosimetry involves the standard specification of doses in tissues that include a large proportion of air, such as the lung. As a single x-ray beam penetrates through water or tissue, the dose received by the tissue falls progressively, generally as an exponential function of distance. Because of its markedly lower density, air absorbs less radiation energy and, therefore, attenuates the x-rays less than does tissue or water. With the quantitative knowledge of lung density derived from CT scanning, algorithms that estimate the inhomogeneity in the absorbed dose resulting from differences in the density of lung and other soft tissues are now regularly used.[11,12] These heterogeneity corrections show that routine dosimetric calculations, which assume uniform density, underestimate the radiation doses to lung and tissues beyond the lung by 5% to 25%.

Although the effect of tissue heterogeneity is now regularly accounted for when quantifying the radiation dose delivered to the lungs, one must remember that doses delivered to the thorax and the lungs historically have been reported in the medical literature *without* heterogeneity corrections. Moreover, because the preponderance of clinical data concerning lung tolerance have been determined and reported using older dosimetric algorithms, which assume that lung has water-equivalent density, the impetus to change dose reporting is tempered by the desire to avoid confusion between the newer and older literature. The reader should assume, unless explicitly stated otherwise, that the historic radiation doses given in this chapter, or for that matter any publication, are not necessarily corrected for lung density. Without such corrections, actual dose delivery to the chest region is modestly higher than the nominal doses reported, but with potentially wide variability prior to computerized treatment planning.

Charged particle therapies, including proton therapy, exploit the unique physical characteristics of charged particles to allow for more precise dose deposition and are rapidly increasing in utilization throughout the world. Protons primarily interact through the Coulomb force with electrons in an organic target material, leading to electron excitation and ionization. These ionized electrons, which have relatively low kinetic energy, then deposit energy close to the site of the original particle interaction. The proton slows as it deposits its energy, increasing the amount of time for electron interaction, which further slows the proton until it stops. This results in most of the dose being deposited near the end of the proton's path, leading to the characteristic depth–dose distribution known as the "Bragg peak." In order to deliver dose to the entire depth of a target, beams with different depths (different beam energies) are summated to create a "spread-out Bragg peak," which also results in a higher entrance dose. The abrupt deposition of radiation dose allows for sparing of normal tissue beyond the target, such as heart or uninvolved lung. However, there are additional dosimetric challenges brought by the stopping power of protons, as accurate depth calculation requires precise knowledge of tissues and may be impacted by daily variation in anatomy.

Radiation dose is currently reported using the unit of the Système International (SI), the gray (Gy). The Gy is a measure of the energy absorbed by 1 kg of tissue; 1 Gy = 1 J/kg. The former unit of absorbed dose, called the "rad" (an acronym for "radiation absorbed dose") was measured with the CGS system: by definition, 1 rad = 100 ergs per gram. To compare old and recent literature, one must remember that 1 Gy = 100 rad. Even though the rad is not an approved SI unit, some radiotherapy literature avoids this conversion by giving the dose in centiGray (cGy), where 1 cGy = 0.01 Gy = 1 rad. Other measures of radiation dose seen in the literature include the roentgen, the Sievert, and the rem.

The roentgen measures radiation *exposure,* rather than energy *absorption,* and refers specifically to the amount of ionization produced in air under standard conditions (1 R = 1 electrostatic unit/cc = 2.58×10^{-4} coulombs/kg of "standard air" at a density of 1.29×10^{-4} g/cm^3 at 0°C and 760 torr). This unit is frequently encountered in the radiation dosimetry literature, not only because it was historically used as a measure of dose, but also because many widely used radiation monitors (e.g., ionization chambers) directly measure radiation exposure at the surface of the body. The dose absorbed by tissue is then calculated from this exposure.

The radiation protection literature uses the unit of "equivalent dose," the Sievert (Sv), which is calculated as the absorbed dose (in Gy) multiplied by a "weighting factor" that considers the differing biologic effects of different radiations. Although the weighting factors for some radiations, such as neutrons and alpha particles, can be as high as 20, the weighting factors for x-rays, gamma rays, and electrons are all defined as 1. For most purposes in diagnostic and therapeutic radiology, therefore, 1 Sv = 1 Gy. The Sv replaces the older unit of equivalent dose, the rem (1 Sv = 100 rem). Unfortunately, the literature on radiation-induced lung injury includes papers using all these different units, creating great confusion for readers. For simplicity, all doses in this chapter have been converted to Gy.

RADIOBIOLOGY OF RADIOTHERAPY

When x-rays pass through tissue, a complex series of physical and chemical reactions occurs.[1,13] As the x-rays interact with atoms along their path, energy is absorbed, and energetic fast electrons are ejected. These fast electrons travel through tissue, producing secondary ionizations, which lead within milliseconds to the generation of a variety of highly reactive free radical species. Because biologic materials are about 70% water, ions and free radicals derived from water (e.g., H, OH, H_2O^+, H_3O^+) are the main reactive species produced. These ions and radicals react with each other and with other nearby molecules, creating a wide variety of chemically reactive species and producing many kinds of damage in biologic macromolecules. Because DNA contains information that is critical to the cell, while most other molecules can be replaced readily, damage to DNA is the most important biologic effect of irradiation. Radiation produces a wide variety of lesions in DNA, including single- and double-strand breaks, damaged bases, and loss of bases, as well as chromosomal breaks and rearrangements. If these lesions are not repaired, the result can be permanent mutations or changes in chromosomal structure that lead to the death of the cell or changes in its behavior.

The cytotoxic effects of radiation are the basis for both the antineoplastic effects and the toxicities of radiotherapy. A theoretical concern is that radiotherapy may produce a mutation in a previously normal cell that leads to the development of a new malignancy. Although radiation-induced malignancies do occur and are a primary concern in considerations of environmental and occupational exposures,[8] malignant transformation is a rare enough event at the doses used in radiotherapy that the risk of inducing a second cancer in an individual patient is typically very small relative to the great benefit of curing the existing malignancy.[10] The greater risk to the patient lies in the fact that radiation is not selectively toxic to the tumor cells, but instead, damages both normal and malignant cells within the treatment field.

Although the radiochemical reactions that lead to cytotoxic damage are complete within milliseconds after the end of irradiation, cells dying from radiation injury do not die immediately. In fact, soon after irradiation, radiation-sterilized cells are indistinguishable from cells that ultimately survive irradiation in their appearance, metabolic activities, and even rates and patterns of proliferation. Most radiation-sterilized cells ultimately die during mitosis, but they may first undergo one or even several divisions, producing an abortive clone of sterile cells, which may later undergo postmitotic cell death. This delayed cytotoxicity underlies many of the effects seen in radiotherapy. Rapidly growing tumors, for example, generally begin shrinking sooner than slowly growing tumors, and many tumors continue to shrink progressively for months after radiotherapy. Analogously, radiation reactions in normal tissues reflect the normal patterns of cell turnover in the tissue.[14,15]

After irradiation, nonproliferating, terminally differentiated cells continue to perform their differentiated functions throughout their normal life spans. Other cells that are not proliferating at the time of irradiation likewise continue to function normally until they are recruited into proliferation, perhaps months or even years after irradiation; when they begin to proliferate, their progeny die. Some cell types, especially hematopoietic cells, may be induced by radiation-induced damage to enter a pathway of programmed cell death that leads to apoptosis. Other mechanisms of cell death that may be activated after radiation include necroptosis and pyroptosis; alternatively, cells may enter a state of senescence, which is characterized by the inability to replicate while remaining metabolically active.[16,17]

A typical survival curve for mammalian cells, obtained using mouse lung cells, is shown in Fig. 57-3. As a first approximation, cell survival falls exponentially as the radiation dose increases. Statistically, this implies that each incremental dose of radiation has the same cytotoxic effect; that is, each incremental dose kills the same proportion of the viable cells that were present in the population at the beginning of that irradiation. Very low doses of radiation have somewhat lesser effects; the shoulder on the cell survival curve reflects the ability of the cells to accumulate and tolerate or repair some of the damage produced by radiation.

The effect of the repair of radiation damage can be seen when the radiation dose is divided into two or more treatments separated by hours or days, rather than being delivered in a large single dose. Dividing, or "fractionating," the radiation dose allows cells to repair damage to their DNA and to proliferate between treatments.[1,10] As a result, there is less cytotoxicity from a fractionated treatment regimen than from the same total radiation dose delivered as a large single fraction (Fig. 57-4). Smaller fractions produce less cytotoxicity than larger fractions. Similarly, the cytotoxic effects of radiation are diminished when the radiation is delivered continuously at a low-dose rate, over hours or days, allowing repair and proliferation to occur during irradiation (Fig. 57-4).

Fractionating therapeutic irradiations or delivering the radiation at low-dose rates generally appears to increase the therapeutic ratio by protecting normal tissues against radiation injury, while producing a smaller increase in the relative radioresistance of the tumor; treatment outcomes are thereby improved. This increase in the therapeutic ratio is thought to reflect qualitative and quantitative

AL GRAWANY

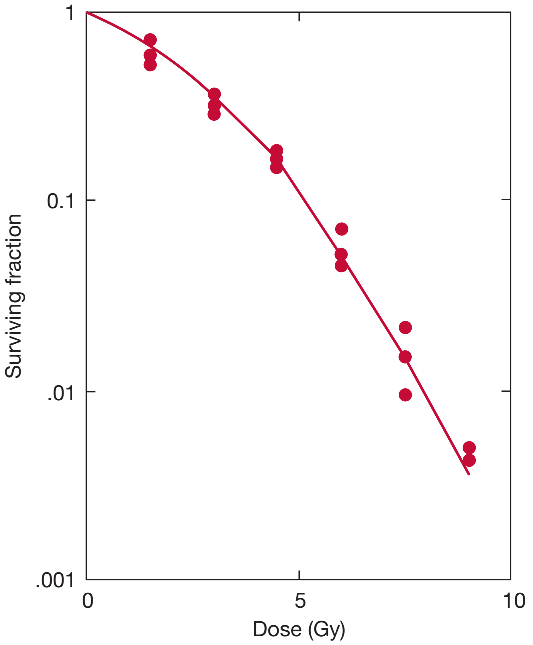

Figure 57-3 Survival of lung cells treated with different doses of radiation. Cells were explanted from mouse lungs, irradiated in vitro, and assayed for viability using a colony formation assay. *(Reproduced with permission from Guichard M, Deschavanne PJ, Malaise EP. Radiosensitivity of mouse lung cells measured using an in vitro colony method. Int J Radiat Oncol Biol Phys. 1980;6(4):441–447.)*

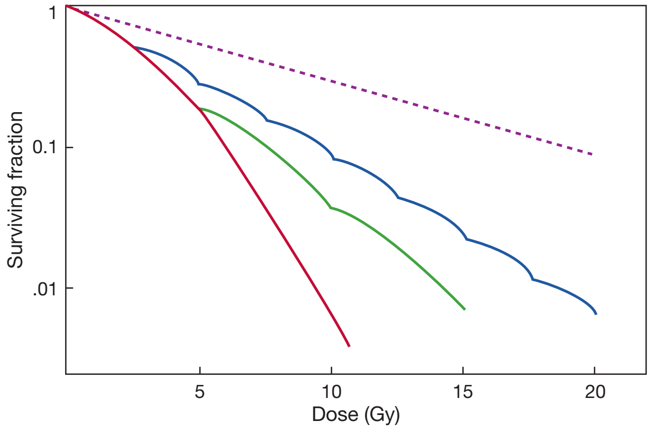

Figure 57-4 Effect of fractionated irradiation and low-dose rate irradiation on cell survival. The survival curve for lung cells treated with a single dose of radiation is redrawn from Fig. 57-3. The calculated effect of dividing the radiation dose into several daily treatments with 5 Gy/fraction or 2.5 Gy/fraction is illustrated. The *dashed line* illustrates the survival curve that would be expected for irradiation delivered continuously at a low-dose rate over several hours, allowing repair and proliferation to occur during treatment. Changes in the cytotoxicity of radiation with fractionation and at low-dose rates lead to decreased injury in lungs irradiated with analogous regimens.

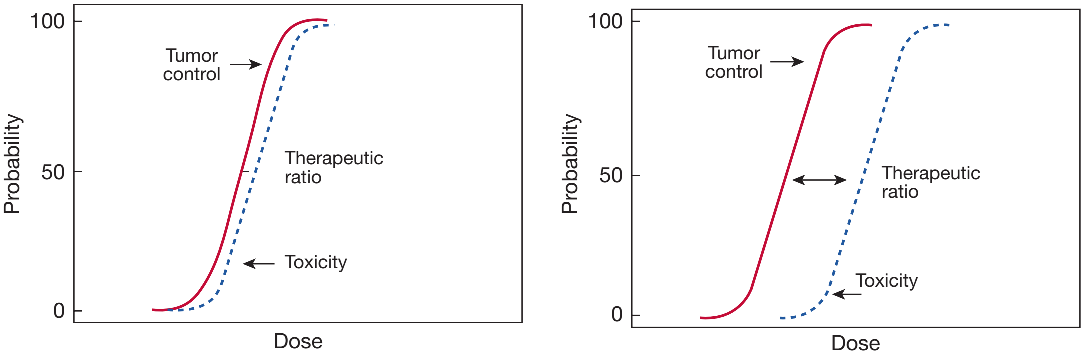
differences between normal and malignant cell populations, including differences in the intrinsic radiosensitivity of the critical cells and in the patterns of cell proliferation and cell loss, as well as differences in the ability of the normal and malignant cells to repair radiation damage. Empiric observations of patients treated with radiotherapy, laboratory experiments with tumors and normal tissues in rodents, and studies with cells in culture have all been used to guide the development of the clinical fractionation schedules now in use. The development of new technologies and techniques that deliver radiation more precisely, such as SBRT, have also allowed for a departure from standard fractionation schedules by reducing the amount of normal tissue exposed to high doses of radiation. Ultimately, any improvement in the delivery of radiation therapy must improve the therapeutic ratio by producing an increased effect on the tumor without an equivalent increase in toxicity to critical normal tissues (Fig. 57-5). The art of radiotherapy lies in the design of treatment fields that minimize radiation doses to normal tissues and in the development of treatment regimens that use all available information on the biology of the tumor and of the critical normal tissues.

PATHOPHYSIOLOGY OF RADIATION PNEUMONITIS

Data on radiation pneumopathy in humans is fragmentary and complicated by the heterogeneity of the patients treated with thoracic irradiation. Most studies of radiation pneumonitis include patients with a variety of malignancies who have been treated with different irradiation regimens, often in combination with chemotherapy and surgery. Moreover, patients vary widely in age and the presence of other diseases and risk factors. Therefore, our current understanding of radiation injury to the lung remains incomplete. What is known suggests a complex, multifactorial mechanism of injury and disease progression that reflects cytotoxic effects on both epithelial and endothelial tissues. Inflammatory responses involved in this injury cascade include transient increases in reactive oxygen and nitrogen species, macrophage infiltration and activation, oxidative



Increasing the therapeutic ratio, either by selectively increasing the effect on tumor or by selectively protecting normal tissues from injury, produces therapeutic gain.

Figure 57-5 The therapeutic ratio is the critical factor determining the success of cancer therapy.

stress, induction of interstitial fibrosis with regional tissue hypoxia, and disordered cytokine and cellular signaling—including profibrogenic transforming growth factor beta (TGF-β), proangiogenic hypoxia-inducible factor 1 alpha (HIF-1α), and vascular endothelial growth factor (VEGF).[5,6,13,18–24] Similarities to lung injuries resulting from cancer chemotherapy, other drugs, inhaled chemicals, oxygen toxicity, immune reactions, and idiopathic pulmonary fibrosis are intriguing, especially when one considers that many of these diseases include pathologic responses to free radical chemical species and are likely to reflect similar underlying initial lesions.

Partial-lung resection and localized irradiation have certain similarities: Their effects are largely localized to the treated areas and, consequently, depend on the number of pulmonary lobules or alveolar–capillary units functionally destroyed. Thus, the volume of lung irradiated is an important determinant of toxicity. Just as the thoracic surgeon plans lung resection with due consideration to anticipated residual lung function, the radiation oncologist plans treatment to minimize the volume of lung and other critical tissues receiving significant radiation doses. Of course, this simple analogy has its limitations. For example, inactivation of enough lobules by radiation increases the ventilatory dead space and could lead to shunting and ventilation–perfusion mismatching. However, in clinical practice, extensive shunting generally is not observed.[25] In fact, post-radiation radionuclide ventilation–perfusion scans tend to show both underperfusion and underventilation that is dose dependent in irradiated areas of partially irradiated lungs.[26] In most cases, radiation injury in lung conforms to the radiation treatment fields, but in some, effects outside the treated areas are observed, with localized radiation inducing a more generalized or diffuse hypersensitivity pneumonitis.[27]

The effects of radiotherapy on the lung reflect the proliferation patterns of the different cellular components of the terminal capillary–alveolar units.[28] Type I pneumocytes are the dominant epithelial cells of the lung, covering about 83% of the alveolar surface. Type I pneumocytes are normally nonproliferating and do not proliferate in response to injury. Consequently, they are thought to be relatively resistant to the cytotoxic effects of radiation.

Type II pneumocytes, which constitute about 16% of the cells in the human lung, are the principal source of surfactant that modifies alveolar surface tension to prevent atelectasis. Type II pneumocytes have turnover times of about 1 month. In response to certain injuries, these granular pneumocytes can be induced both to undergo rapid mitosis and differentiate into type I pneumocytes.

Endothelial cells constitute about 30% of the cells in human lungs and form a continuous layer between the blood and the lung tissue. Although endothelial cells are classified in most tissues as stromal cells, endothelial cells in lung are actually parenchyma, because they are critical to the function of this organ. Capillary endothelial cells are a constantly renewing population, with an estimated turnover time on the order of 2 months. Endothelial cells can be induced into rapid compensatory proliferation after injury; therefore, radiation may result in depletion of both type II pneumocytes and endothelial cells.

Several lines of evidence suggest that radiation injury is related primarily to cytotoxic damage, especially to the surfactant-producing type II pneumocytes and vascular endothelial cells. Although clinical signs of pneumonitis require weeks to develop, laboratory studies reveal evidence of lung injury beginning just hours after large single doses of radiation.[23,29–32] Shortly after irradiation, electron microscopy may detect abnormalities in surfactant-containing lamellar bodies. There is an increase in surfactant in bronchoalveolar lavage specimens within hours of irradiation that persists for several weeks. Ultrastructural evidence of endothelial cell damage is also seen soon after lung irradiation, and a rapid increase in capillary permeability occurs, reflecting loss of integrity of cell junctions, intracellular vacuolization, cellular pleomorphism, and sloughing of the basement membrane. Capillary occlusion by cellular debris and microthrombi may occur at high doses.

The clinical course of lung injury occurs later and includes a pneumonitic phase, developing weeks to months after radiation, followed by a fibrotic phase, developing months to years later. To explain the two clinical phases, Rubin's and Casarett's original model of radiation lung toxicity suggested that the pneumocytes and endothelium represented two separate and distinct cellular targets, and that damage to pneumocytes led to pneumonitis, while vascular damage led to fibrosis. This older model is now thought to be incorrect; more recent data[21–23,28,33–38] suggest that the pneumonitic and fibrotic processes both are manifestations of a common pathway of injury and response.

There is a typical sequence of events that develops in the lung after large doses of radiation.[19,29,30] Within hours to days, vascular congestion and intra-alveolar edema and exudation occur, followed by infiltration of inflammatory cells and epithelial desquamation. Weeks later, collagen fibrils are deposited within areas of injury and interstitial edema, leading to a thickening of alveolar septa similar to that in hyaline membrane disease. The probability and severity of these changes are quite variable and depend on such factors as the radiation dose and treatment volume. The severity of the damage and volume of tissue affected determine whether a pneumonitic picture becomes clinically evident. Resolution of inflammatory infiltrates and alveolar exudates, which can be improved by anti-inflammatory agents such as glucocorticoids, correlates with symptomatic improvement and resolution of radiographic opacities in the affected lung.

Inflammatory cells, particularly alveolar macrophages, migrate into areas of radiation injury. This induces an ensuing cytokine cascade and mediates the host response,[6,20,22,23] similar to that which occurs in other inflammatory conditions, which can lead to pulmonary fibrosis. Rubin et al. detected a biphasic increase in mRNA expression for the proinflammatory cytokines IL-1α, IL-1β, and TNF-α at 2 and 8 weeks after radiation.[23] Beginning 24 h following radiation, TGF-β, a cytokine that mediates fibrotic responses, increases.[19] Elevated levels of VEGF may be detected 2 weeks later. Early clinical trials also suggest that elevated serum levels of IL-6 before, during, and after radiotherapy predict an elevated risk of radiation pneumonitis.[39,40] While TGF-β has been extensively studied and is thought to be a culprit for radiation-induced fibrosis in multiple organs-at-risk, clinical data have been mixed. One initial trial showed increased serum TGF-β levels at the end of radiation in patients who developed pneumonitis, but an additional prospective trial did not show a correlation with pneumonitis.[41,42] Collagen gene expression is also appreciably increased corresponding to the fibrotic changes seen histologically. These studies suggest that early and persistent elevations of cytokine production and alterations of intercellular signaling are critical to the development of radiation reactions in the lung. Similarly, ICAM-1, which promotes neutrophil transmigration into the damaged lung, is found in increased levels in blood of patients with pneumonitis at the end of radiation therapy and at the onset of pneumonitis.[43] ICAM-1 knockout mice that undergo radiation therapy have less inflammatory cell infiltration into the lung and decreased pulmonary fibrosis.[44,45]

Murine models demonstrate that genetic differences, age, and past health and treatment history can modulate the development and severity of fibrosis and hyaline membrane formation, thus determining the nature of the late toxic lesion and the time of development of radiation pneumotoxicity.[6,33,34] Single nucleotide polymorphisms in genes for methylene tetrahydrofolate reductase (MTHFR) and ataxia telangiectasia mutated (ATM) have been associated with development of symptomatic pneumonitis and severe pneumonitis.[46–48]

The processes described earlier lead to pathologic changes that conform spatially to the areas to which localized radiation was administered. Interestingly, it has been discovered that radiation can also induce an allergic alveolitis. This is observed infrequently as a diffuse pneumonitis, or occasionally as a patchy, transient cryptogenic organizing pneumonia (COP, previously known as bronchiolitis obliterans organizing pneumonia [BOOP]) occurring outside the treated fields. In its most severe form, the result is the acute respiratory distress syndrome (ARDS). Morgan and Breit[27] have suggested that this form of radiation-induced pneumonitis be termed "sporadic." The occurrence of the syndrome actually may be more common than appreciated. One series showed a 2.3% incidence of COP in women undergoing whole breast radiotherapy, occurring outside the radiotherapy fields four or more months after exposure.[49] Bronchoalveolar lavage in humans and in experimental animals frequently shows a significant increase in activated T-helper ($CD4^+$) lymphocytes, temporally related to irradiation and occurring equally in the irradiated lung and the contralateral, nonirradiated lung.[50] Gallium scanning may also show bilateral uptake not corresponding to the treated regions. Frequent reports of autoantibodies, including antibodies to collagen, in the sera of patients with cancer even before treatment suggest the possibility that malignancy-associated autoimmune reactions may be involved in the syndrome.

CONFOUNDING EFFECTS OF SYSTEMIC THERAPIES

Special consideration needs to be given to patients receiving additional systemic therapies along with radiation treatment, including chemotherapy and immunotherapy.

Chemotherapy

Many cytotoxic drugs employed as antineoplastic agents can produce pulmonary toxicity.[51–53] Bleomycin, which has been extensively studied, kills cells by generating reactive free radical species similar to radiotherapy and may give rise to both pneumonitis and fibrosis.[51] Doxorubicin, mitomycin C, irinotecan, etoposide, and gefitinib have been associated with lung toxicity, as have the antimetabolites (methotrexate, cytosine arabinoside, gemcitabine, fludarabine, and the nitrosamines) and the taxanes (paclitaxel and docetaxel).

As high-dose alkylating agent chemotherapy is used more frequently in the setting of stem cell transplantation, agents such as cyclophosphamide, BCNU, and busulfan have been associated increasingly with clinically significant pneumonitis. The direct toxicity of many widely used anticancer drugs to the lungs sounds a note of caution for those considering development of treatment protocols combining systemic chemotherapy with lung irradiation. Moreover, the concurrent administration of antineoplastic agents and radiotherapy may make it difficult to discern to what degree pulmonary injury in an individual patient is related to radiotherapy alone.

Animal studies addressing changes in respiratory rates and/or death resulting from lung injury show that the severity of the lung injury can be increased when doxorubicin, bleomycin, cyclophosphamide, mitomycin C, dactinomycin, or vincristine is administered along with radiation.[54,55] No enhancement has been documented in studies with 5-fluorouracil, cisplatin, carboplatin, hydroxyurea, vinblastine, or methotrexate, despite reports of lung toxicity from methotrexate alone.

Some radiation–drug interactions in the lung have been shown to be schedule dependent, with the effect of the combination varying with the sequence and the time between treatments with the two agents.[54] Additive, sub-additive, and even supra-additive toxicities may be observed in rodents when single treatments with the same dose of radiation and drug are given over a 24-h period, but in different sequences and different times between treatments. Such findings highlight the complexities of combined-modality therapy and the difficulty of using animal data to plan clinical treatment regimens.

Data from several specific clinical situations show that regimens combining radiation with particular chemotherapy agents can produce significant risks of pneumonitis. Docetaxel, mitomycin C, gemcitabine, and irinotecan given concurrently with radiotherapy seem to elevate the risk of pneumonitis or lung toxicity, while concurrent treatment with cisplatin and etoposide has a lower risk.[56,57] Concurrent weekly paclitaxel is associated with increased risk of radiation pneumonitis in patients with breast cancer.[58] Older clinical data from pediatric trials strongly suggest that administration of concurrent doxorubicin or actinomycin D with thoracic radiotherapy generally should be avoided or, alternatively, that the radiation doses should be reduced significantly where these drugs are used. These data are also supported by studies of anthracycline use in breast cancer patients.[59]

Sequential treatment with radiation and chemotherapeutic agents such as gemcitabine, actinomycin D, or doxorubicin is less likely to produce lung injury compared with concurrent treatment. However, a phenomenon termed "radiation recall" has been well described, in which chemotherapy administration even several months after radiotherapy will produce an inflammatory reaction in the region corresponding to the radiation treatment fields.[60] Although this reaction is best known in skin, it also has been well documented in the lungs in several case reports and has been produced in experimental animals. This has been reported with multiple chemotherapies including gemcitabine, doxorubicin, paclitaxel, etoposide, and pemetrexed. Radiation recall probably reflects the fact that the irradiated areas of the lung still retain residual, subclinical injury, which is exacerbated into clinical pneumonitis as a result of the additional injury from the drug. Therefore, the biologic basis of the recall phenomenon is analogous to that of the residual radiation injury, which decreases the ability of heavily irradiated lung tissue to tolerate a second course of radiotherapy delivered months or years later.[29,37]

Immunotherapy

Treatment with immune checkpoint inhibitors (ICIs) has become a staple of oncologic care in multiple settings. It is now part of first-line treatment for locally advanced and metastatic non–small-cell lung cancer (NSCLC) as well as extensive-stage small-cell lung cancer. As the indications for immunotherapy continue to expand, an understanding of its interaction with radiation therapy will be critical for physicians who treat cancer patients. The combination of radiation therapy and immunotherapy is particularly intriguing due to theoretically synergistic effects, with some hypothesizing that increased antigen presentation caused by damage from radiation may increase the efficacy of immunotherapy.[61,62] Multiple ongoing trials are assessing the safety and efficacy of the combination of thoracic radiotherapy and immunotherapy, either concurrently or sequentially.

Checkpoint inhibitors are immunomodulatory antibodies that enhance the immune system by interfering with inhibitory interactions between T cells and antigen-presenting cells. Antibodies to programmed death 1 (PD-1), programmed death ligand 1 (PD-L1), and cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) constitute most of the current checkpoint inhibitor armamentarium, and other potential targets are in development. While increased recognition of tumor by the immune system is desired, checkpoint inhibitors carry risk of adverse events related to general immunologic enhancement (immune-related adverse events), including pneumonitis. The risk of pneumonitis from PD-1 inhibition alone is typically less than 5% in clinical trials, with one meta-analysis demonstrating a 4.1% risk of any-grade pneumonitis in NSCLC patients and 1.6% in melanoma patients.[63] However, real-world populations may have additional risk factors and carry a higher risk of pneumonitis, with retrospective studies showing estimates of checkpoint inhibitor pneumonitis as high as 19%.[64] When given sequentially, immunotherapy and thoracic radiation appear to be safe with a mild increased risk of pneumonitis compared with radiation alone. In the PACIFIC trial, patients were randomized 2:1 to consolidation durvalumab or placebo after chemoradiation, with 92% of patients treated to doses between 54 and 66 Gy. Any-grade pneumonitis was observed in 33.9% of the durvalumab group versus 24.8% in the placebo group; grade 3 or 4 pneumonitis rates were 3.4% and 2.6%, respectively.[65] Retrospective data also have showed a mildly increased risk of pneumonitis after sequential chemoradiation and immunotherapy, with one study showing an 18% risk of grade ≥2 pneumonitis compared with 9% in a historic cohort of patients treated with chemoradiation alone.[66] The combination of SBRT and adjuvant immunotherapy has acceptable toxicity in early phase 1 and 2 trial data, with grade 3 pneumonitis rates typically under 5%.[67,68] However, the presence of pneumonitis in a patient treated with radiation and immunotherapy may portend improved disease response to immunotherapy, with some data suggesting that patients with immune-related adverse events after SBRT and immunotherapy have improved progression-free survival.[69]

An approach utilizing immunotherapy concurrent with radiotherapy is also under active investigation, with early reported data showing this appears to be safe. In an analysis of three clinical trials combining immunotherapy before and after radiotherapy at MD Anderson Cancer Center, grade 3 pneumonitis was reported in 2 of 60 patients treated with SBRT (up to 50 Gy in 4 fractions), 1 of 53 patients treated with 45 Gy in 15 daily fractions, and 1 of 25 patients treated with 45 Gy in 30 twice-daily fractions.[70] In a separate, retrospective, single-institution analysis of concurrent (within 30 days) immunotherapy with radiation therapy, grade 3 pneumonitis was 10.7% with SBRT and immunotherapy compared with 0% with SBRT alone.[71] Early-phase clinical trials have also demonstrated reasonable safety when adding immunotherapy to concurrent chemoradiation, with a 6.9% to 8% risk of pneumonitis for 214 patients treated with pembrolizumab, radiation, and cisplatin/pemetrexed or carboplatin/paclitaxel.[72,73] Final results of larger randomized trials will be needed better establish the safety and efficacy of concurrent radiation and immunotherapy.

In a patient who is treated with both immunotherapy and radiation therapy and develops pneumonitis, it may be difficult to differentiate whether pneumonitis was caused by radiation, immunotherapy, or both. However, there are several potential differences in the spatial and temporal presentation of radiation pneumonitis and immunotherapy-induced pneumonitis that may allow for this distinction. Radiation pneumonitis most commonly occurs weeks to months after radiation therapy, while immunotherapy typically causes pneumonitis while on treatment. Further, radiation pneumonitis may be more likely to correlate with the geographic distribution of the high-to-intermediate dose field. Treatment for both entities is similar (high-dose glucocorticoids), but differentiating the etiology may influence the decision whether to continue or discontinue the immunotherapy. The clinical presentation and treatment of radiation pneumonitis are further detailed below.

■ CLINICAL SYNDROMES

Radiation oncologists conventionally divide clinical toxicities into acute and late effects,[5,6] with both radiation pneumonitis and fibrosis considered late toxicities. Several grading systems for pneumonitis have been developed, with the most commonly used system being the Common Terminology Criteria for Adverse Events (CTCAE) (Table 57-1).

■ Clinical Manifestations During Treatment

It is relatively uncommon to observe acute pulmonary toxicity during the administration of fractionated radiotherapy. However, at relatively high therapeutic doses (50–60 Gy), acute radiation changes in the tracheobronchial tree can be expected. Bronchoscopic examination is likely to reveal erythematous mucosa, with thickened secretions that can accumulate in and obstruct the airways. Although a majority of patients remain asymptomatic, occasional patients experience an irritative, dry cough. Antitussive agents, such as codeine, adequate hydration, and reassurance are usually all that are required to manage this problem. After radiotherapy completion, the bronchial epithelium regenerates and heals over several weeks, accompanied by resolution of symptoms.

■ Subacute to Late Manifestations

The clinical course of late radiation injury to the lungs is biphasic, with both inflammatory and fibrotic components.[21,30,32]

Radiation Pneumonitis

A pneumonitic process frequently becomes evident 6 weeks to 6 months following radiotherapy. At this time, radiographs show alveolar opacities that generally conform to the treatment portals or the areas of high-to-intermediate dose radiation. The severity of radiation pneumonitis varies dramatically from patient to patient, even in those receiving identical therapeutic regimens. In most cases, the pneumonitis is asymptomatic, even though radiologic abnormalities are quite common, as noted in some prospective studies, in which as many as 50% of patients who have completed a course of thoracic radiotherapy were asymptomatic.

TABLE 57-1 CTCAE Version 5.0 for Radiation-Induced Lung Injuries

	Grade				
Term	**1**	**2**	**3**	**4**	**5**
Pneumonitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADL	Severe symptoms; limiting self-care ADL; oxygen indicated	Life-threatening respiratory compromise; urgent intervention indicated (e.g., tracheotomy or intubation)	Death
Pulmonary fibrosis	Radiologic pulmonary fibrosis <25% of lung volume associated with hypoxia	Evidence of pulmonary hypertension; radiographic pulmonary fibrosis 25%–50% associated with hypoxia	Severe hypoxia; evidence of right-sided heart failure; radiographic pulmonary fibrosis >50%–75%	Life-threatening consequences (e.g., hemodynamic/pulmonary complications); intubation with ventilatory support indicated; radiographic pulmonary fibrosis >75% with severe honeycombing	Death

CTCAE, common terminology criteria for adverse events; ADL, activities of daily living.

When symptomatic, this syndrome is often characterized by the abrupt onset of fever, cough, and dyspnea. The severity of symptoms depends on the extent of radiotherapy, increasing with the treated volume and with the radiation dose. Symptoms in patients irradiated to limited lung volumes or to relatively low doses may consist of low-grade fever, cough, congestion, and chest fullness or discomfort. Any hemoptysis tends to be minimal. In more severe situations, dyspnea, high fever, and cough occur. Malaise, weight loss, and chest pain from pleuritis or other etiologies also can be present. When large volumes of normal lung receive radiation dose, acute radiation pneumonitis is more likely and can be extremely severe, producing respiratory distress. The radiation oncologist is probably most likely to see clinically significant radiation pneumonitis that can be life-threatening when it occurs as an unanticipated consequence of standard treatment, despite appropriate treatment planning designed to minimize the volume of lung treated with high doses of radiation. However, the risk for serious toxicities may be higher in patients with pre-existing pulmonary comorbidities, and those with a large burden of locoregional disease for whom it is necessary to radiate a larger volume of lung to achieve potentially curative doses to the tumor. Mild pneumonitis is not uncommon but is readily manageable.

It is important to distinguish radiation pneumonitis from infection, recurrent tumor (particularly with lymphangitic spread), drug reactions, congestive heart failure, and other respiratory disorders. These distinctions may not be easy; one series from Duke suggested 28% of patients with radiation-associated lung toxicity have complex comorbidities that make it difficult to assign a definitive diagnosis.[74] Bacterial, fungal, viral, and pneumocystis pneumonias can be quite difficult to differentiate from pneumopathy induced by chemotherapy or radiation.

Aids in the differential diagnosis include the clinical course and temporal relationship between the irradiation and respiratory illness. Definition of the radiographic pattern of the infiltrate is also very useful, because radiation pneumonitis often conforms to area of higher dose radiation. While classically radiation pneumonitis conforms to radiation ports, a clear delineation may not be as apparent with modern radiation techniques such as IMRT **(Fig. 57-1)**. Bronchoscopy and lung biopsy also can be helpful diagnostic tools to direct therapeutic decisions, especially if other differential diagnoses can be ruled out with bronchoalveolar lavage or tissue pathology. Ruling out infection is particularly important, because treatment of symptomatic radiation pneumonitis relies on supportive care in conjunction with corticosteroids. Procalcitonin may be a useful marker to help differentiate bacterial pneumonia and pneumonitis; one study demonstrated patients with bacterial pneumonia have higher procalcitonin levels compared with radiation pneumonitis, with an area under the receiver operating characteristic (ROC) curve of 0.745 and a suggested cutoff value of 0.47 μg/L.[75]

Most studies show at least a transient decline in pulmonary function in patients who receive radiation to a significant lung volume (i.e., patients with lung cancer receiving a potentially curative course of fractionated radiotherapy). There may be a transient reduction in lung volumes such as total lung capacity (TLC) and forced vital capacity (FVC) 3 to 6 months post-radiation. Carbon monoxide diffusing capacity (DL_{CO}) may be reduced over a similar time course, but typically to a greater degree relative to baseline.[76,77] Absent the development of radiation fibrosis, these parameters tend to recover toward the patient's baseline, reaching maximal recovery at approximately 12 months.

Doses of glucocorticoids generally can be tailored to the severity of the symptoms. Asymptomatic pneumonitis may be managed with close observation. Severe cases generally warrant treatment with prednisone (or its equivalent) at a dose of 0.5 to 1 mg/kg per day in divided doses. Patients who are appropriately diagnosed and treated with high-dose steroids typically respond well, and dramatic clinical and radiographic responses are possible. Steroids should be tapered slowly after the patient is stabilized, because it is common to see a recrudescence of symptomatology when steroids are discontinued too rapidly. In these cases, reinitiation of higher doses and a slower steroid taper, such as 8 to 12 weeks, is recommended. Prophylaxis against *Pneumocystis* pneumonia should be considered due to a potentially prolonged steroid course. Failure to respond to steroid therapy is an adverse prognostic factor that suggests the prospect of rapid disease progression. Other immunosuppressive agents such as azathioprine and cyclosporine can also be considered in patients who cannot tolerate steroids or who have refractory disease, but evidence supporting these therapies is limited.[78,79]

Radiation Fibrosis

A more indolent fibrotic process may follow either subclinical or symptomatic radiation pneumonitis.[21,30,32] This begins several months after radiotherapy and peaks in radiographic severity several years later. Fibrosis tends to occur in, or adjacent to, areas of prior pneumonitis,[33] but it can also occur in the absence of clinically overt radiation pneumonitis. Fibrotic changes and the retraction of the lung parenchyma from scarring occur in the irradiated regions. When the volume of lung irradiated is relatively small and the remaining lung parenchyma contains sufficient respiratory surface area, the changes tend to be asymptomatic.

With increasing relative volumes of pulmonary fibrosis, a spectrum of symptomatology is possible, ranging from mild dyspnea on exertion to severe fibrosis with respiratory compromise, chronic cor pulmonale, cyanosis, and finger clubbing. At the severe end of the spectrum, the syndrome can be life-threatening. In general, in the absence of other underlying lung disease, symptoms are mild when less than 25% to 30% of total lung parenchyma is involved.

While most radiation fibrosis in most patients is asymptomatic, especially with more focal treatments such as SBRT, a small change in pulmonary function testing is expected. One prospective study of patients treated with lung SBRT demonstrated 3.5% to 5.7% decreases in forced expiratory volume in 1 second (FEV_1), DL_{CO}, FVC, and TLC at 1 year, and persistent declines in FEV_1 (7.6%) and FVC (8.9%) at 2 years.[80] Although statistically significant, these changes were rarely clinically significant.

Treatment options for radiation fibrosis are supportive, including oxygen supplementation and pulmonary rehabilitation. Anti-inflammatory treatments like glucocorticoids are not expected to be beneficial and should be avoided due to unnecessary toxicity.

Radiation-induced Pleural Reactions

Pleuritis may also be seen 2 to 6 months following radiation. It can be associated with pleuritic chest pain, a pleural friction rub, and an exudative pleural effusion. Large effusions are, however, distinctly unusual in the absence of other pathology. Like radiation pneumonitis, radiation-induced pleuritis may heal without significant residue, or it may proceed through a fibrotic phase that generates pleural thickening.

Radiation-induced Bronchial Stenosis

With improvements in the technical delivery of radiotherapy, recent clinical trials for lung cancer have emphasized escalation of the administered radiation dose. Because SBRT delivers significantly higher biologically effective doses than are feasible with conventional fractionated radiotherapy, there is an increased risk of bronchial stenosis when delivering SBRT to central tumors. For tumors close to the hilum, radiation-induced fibrosis may result in bronchial stenosis or necrosis, causing post-obstructive atelectasis, volume loss, and functional impairment.[81–83] Severe bronchial injury is rare with fractionated chest radiotherapy using conventional doses. However, with doses beyond those typically prescribed with fractionated radiation, bronchial stenosis becomes more likely; one retrospective series in which radiation doses ranged from 70.8 Gy to 86.4 Gy demonstrated that radiation-induced bronchial stenosis may occur in up to 25% of patients, and incidence directly correlates with radiation dose.[84]

In general, the risk of serious complications after SBRT is elevated for central lung tumors, and particularly for "ultracentral" tumors, which border or nearly border the mainstem bronchi. One study reported a 15% risk of fatal pulmonary hemorrhage in patients treated with 60 Gy in 12 fractions for ultracentral NSCLC, half of which had endobronchial tumor present.[85] Another prospective trial testing a regimen of 56 Gy in 8 fractions reported high rates of severe toxicity, including grade 5 events in 10 of 65 patients with tumors within 1 cm of the main bronchi and trachea.[86] Endobronchial tumor invasion may also contribute to the risk of fatal hemorrhage, and risk of tumor recurrence must be weighed against that of severe radiation toxicity. SBRT regimens for central tumors typically employ lower doses or greater fractionation than for more peripheral tumors.[87,88]

DEFINING THE RADIATION TOLERANCE OF THE LUNGS

Radiation tolerance is typically defined as the dose that yields a 5% risk of severe late radiation injury. When discussing the tolerance of the lungs, one must consider several different therapeutic situations. The tolerance of the lung varies with the volume of lung tissue irradiated.[89] In addition, single-dose irradiations, fractionated irradiations, and irradiations given at low-dose rates each pose different risks of injury, and therefore they must be considered separately. Additional injury from surgery, chemotherapy, or a prior course of radiotherapy also must be considered, as must the confounding effects of injury to lung tissue from coexisting cardiopulmonary disease and from the underlying malignancy. The clinical endpoints used to define a case of radiation pneumonitis vary as well, because the severity of the lung injury spans a wide spectrum of diagnostic signs and clinical symptoms.

With three-dimensional imaging and dose calculation, the dose-volume determinants of pulmonary toxicity have been explored in depth. In 2010, the available data on three dimensional dose-volume determinants of normal tissue injury were compiled in an effort known as QUANTEC (Quantitative Analysis of Normal Tissue Effects in the Clinic).[89] More recently, with the wide adoption and use of hypofractionated radiation, a similar project for SBRT regimens has been published, named HyTEC (Hypofractionated Treatment Effects in the Clinic).[90] Despite these efforts, the medical literature that defines the risks for radiation pneumonitis and fibrosis is extremely complex and often difficult to interpret due to the great heterogeneity of clinical circumstances and biologic data.

■ Whole-lung Irradiation

A good starting point for considering lung tolerance is analysis of the effects of irradiating the entire lung. This construct has direct clinical relevance because there are several circumstances in which the entire lung is irradiated. These include total-body irradiation (TBI) for bone marrow or hematologic stem cell transplantation, and whole-lung irradiation given electively or therapeutically for relatively radiosensitive tumors, such as Wilms tumor or Ewing sarcoma. These are often circumstances in which chemotherapy is administered as well.

TABLE 57-2 Actuarial Incidence of Radiation Pneumonitis After Single-fraction Whole-lung Irradiation

Uncorrected Dose	Patients	Pneumonitis (%)
<6 Gy	49	2.7
6 Gy	24	17.5
8 Gy	149	35.6
10 Gy	23	83.9

Note: Doses are not corrected for heterogeneity in tissue density.
Data from Fryer CJ, Fitzpatrick PJ, Rider WD, et al. Radiation pneumonitis: experience following a large single dose of radiation. Int J Radiat Oncol Biol Phys. 1978;4(11–12):931–936.

Published experience from the Princess Margaret Hospital in Toronto[12,91–93] provides some of the best data regarding whole-lung tolerance. Investigators from that institution have an extensive experience with delivering upper hemibody irradiation in different doses and varying fractionation patterns. They reported in 1978 on a cohort of 245 patients, most with metastatic solid tumors, who received single-fraction, upper hemibody irradiation at dose rates of 0.3 to 0.8 Gy/min to doses of up to 10 Gy.[91] The actuarial incidence of acute radiation pneumonitis, defined as the sudden onset of cough, dyspnea, and opacities visible on chest radiographs at about 16 weeks following treatment, was strikingly dose dependent (Table 57-2). The doses shown in Table 57-2 were not corrected for heterogeneity in density.[12] When doses are corrected, resulting in an upward estimation of the doses actually received by the lungs, analysis yielded the sigmoid-shaped curve shown in Fig. 57-6.[94–96]

Using heterogeneity-corrected data, the incidence of pneumonitis is estimated to be negligible for single doses less than about 7.5 Gy. Other published data regarding upper hemibody single-fraction irradiation are in general agreement with these findings.

Careful analysis suggests that the single-fraction data might predict an unacceptable risk for pneumonitis when single-fraction TBI is utilized in the setting of bone marrow transplantation (BMT). The most important treatment factor making single-fraction TBI in the range of 8 to 10 Gy (uncorrected for heterogeneity) tolerable is that treatments generally are given at a low dose rate ($\leq$0.1 Gy/min) over 1 to 2 h.[38,97] In Seattle, where hundreds of patients with leukemia have undergone BMT after TBI, using single fractions of 10 Gy (uncorrected) delivered at dose rates on the order of 0.08 Gy/min,

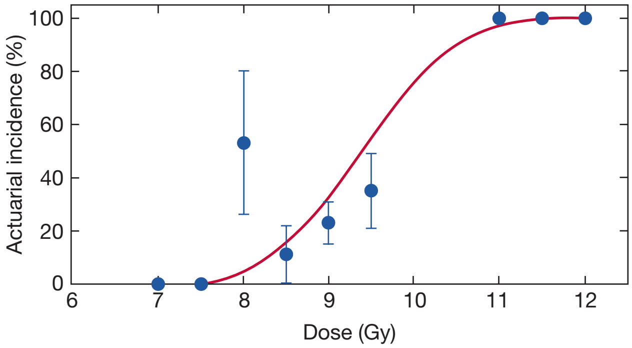


Figure 57-6 Incidence of radiation pneumonitis in patients receiving single-dose, whole-lung irradiation at dose rates of 0.3 to 0.8 Gy/min. Unlike most doses given in the text, doses on this figure *are* corrected for heterogeneity in density. The effect of this correction can be seen by comparing these data with those in Table 57-1, which were derived from an earlier analysis by the same group and are presented using uncorrected doses. *(Reproduced with permission from Van Dyk J, Keane TJ, Kan S, et al. Radiation pneumonitis following large single dose irradiation: a re-evaluation based on absolute dose to lung. Int J Radiat Oncol Biol Phys. 1981;7(4):461–467.)*

the incidence of pneumonitis is roughly 25%. Review of transplant-related single-fraction TBI with variable dose rates shows incidences of clinical lung injury varying from 25% to 70%.[92,98,99]

Toxicities of TBI can be improved further by fractionating the irradiation, as well as by delivering radiation at a low dose rate. In a randomized clinical trial comparing low-dose-rate, single-fraction TBI (10 Gy) with low-dose-rate, fractionated TBI (12 Gy in 6 fractions over 3 days) for patients with acute myelogenous leukemia in first remission, a significant improvement in event-free survival was noted with fractionation, mainly because of an improvement in early mortality.[97] Interstitial pneumonitis was decreased from 26% to 15% with fractionation. Other studies have corroborated a reduced incidence of pneumonitis to less than 20% without increasing the rate of tumor recurrence using fractionated TBI.[96,100,101] Within a range of 1.5 to 2 Gy per fraction given once or twice daily, there is no significant increase in pneumonitis risk using doses up to 15 Gy. Nevertheless, total dose delivered to the lung is a key determinant of pneumonitis risk.[92,102] In addition, at many transplant centers it has become common practice to utilize lung transmission blocks to attenuate the lung dose and thereby reduce the risk of pneumonitis, in part by compensating for the heterogeneity in tissue density due to the air within the lungs.

Lowering the dose rate of radiation delivery is typically also employed for fractionated TBI. Within the context of fractionated TBI schemes, instantaneous dose rates of 0.05 to 0.18 Gy/min generally have been employed due to practical considerations; while efficacious,[103,104] treatment times of 2 to 3 hours are impractical and poorly tolerated by patients. Whether or not higher instantaneous dose rates are detrimental in the context of fractionated TBI and lung transmission blocks remains unclear. One small study comparing dose rates of 0.075 versus 0.15 Gy/min for TBI prescribed to 12 Gy in 6 fractions reported pneumonitis risks of 13% and 43%, respectively, for these dose rates, although there were many confounding covariates.[105] Retrospective analysis of pediatric ALL patients receiving TBI as part of a myeloablative allogeneic transplant preparative regimen from both Emory and University of Minnesota show a lower risk of pneumonitis with lower instantaneous dose rates.[106,107] Another analysis of pediatric patients receiving TBI within the Children's Oncology Group experience showed that total dose to the lungs (factoring in lung blocking) rather than dose rate was a dominant risk factor for pneumonitis, suggesting that mean lung doses above 8 Gy had higher risk.[108] Contributing to pneumonitis risk was the use of lateral whole-lung fields compared with anteroposterior-oriented beams. This was loosely corroborated by investigators at Duke.[109]

Pneumonitis in the BMT setting has a multifactorial etiology, reflecting not only the effects of radiation, but also the effects of chemotherapy, graft-versus-host disease (GVHD), lung injury from tumor, opportunistic infections, and other risk factors.[98,100] Cyclophosphamide is almost universally given with TBI. The addition of other drugs is based on institutional treatment policies; many of these anticancer drugs are known to injure the lung.[51,53] In fact, BMT conditioning regimens that do not use TBI (which often use high-dose busulfan in place of radiation) have rates of interstitial pneumonitis comparable to regimens that include TBI. The presence of GVHD also is important, not only because GVHD causes lung injury directly, but also because the drugs used to control GVHD injure the lung. Perhaps, for this reason, T cell–depleted transplants, which produce less GVHD, tend to have lower risk for pneumonitis.[110]

Whole-lung irradiation has been used in the treatment of widespread lung metastases. In two published series, a combined total of 70 patients with osteosarcoma who received elective whole-lung irradiation to prevent pulmonary metastases received 15 to 17.5 Gy in 10 fractions. None of these patients developed pneumonitis.[21] Similarly, in a series of 40 patients who received 20 to 25 Gy of thoracic irradiation in 1.5-Gy fractions to treat pulmonary metastasis, no cases of pneumonitis were reported.[21] This and other clinical experience with fractionated whole-lung irradiation in the nontransplant setting and in the absence of chemotherapy indicate that 25 Gy in 20 daily fractions over 4 weeks or 20 Gy in 10 daily fractions over 2 weeks should have a relatively low risk (<5%) for radiation pneumonitis.

Historically, radiotherapy for Hodgkin disease had included whole-lung treatment in situations in which there is massive mediastinal adenopathy, hilar adenopathy, or overt pulmonary disease treated with chemotherapy. Risks of symptomatic pneumonitis ranging from 7% to 35% have been reported, with the risk highly dependent on the total radiation dose and the fractionation pattern.[21,111] When the whole lung is to be irradiated, available data suggest that the lungs should be treated through transmission blocks, rather than using open fields. This reduces both the total dose and the dose per fraction to the lungs, thereby reducing the risk of symptomatic pneumonitis to 4% to 7% over a broad range of total lung doses of 10 to 20 Gy.

Lung radiotherapy using 12 to 14 Gy for pulmonary metastases in pediatric patients with Wilms tumor (who also receive sequential doxorubicin and actinomycin D) is associated with a 10% incidence of pneumonitis.[112] Long-term follow-up in such children also shows restrictive lung disease, with total lung and vital capacities approximately 70% of the predicted values. In children receiving thoracic irradiation, inhibition of normal growth and development of the lung parenchyma and bones as a result of radiotherapy also produces significant morbidity. The effects of radiation on growth and development and the radiosensitivity of growing tissues raise special concerns in the treatment of pediatric patients.[10]

■ Partial-lung Irradiation

Estimating the risks of radiation pneumopathy for individual patients receiving radiotherapy is a daunting task, because so many confounding factors must be considered. With lung cancer, the tumor size and location influence the volume of adjacent normal lung that must be irradiated. The volume irradiated should determine the number of capillary–alveolar units destroyed and, therefore, should influence the risk of symptomatic radiation pneumonitis and fibrosis.[28] This qualitative prediction is borne out by clinical experience, but quantifying the risks is not straightforward. The lung region irradiated also is important, because the upper lung regions contribute less to gas exchange than do the lower regions. Treatment-related factors such as total dose, dose per fraction, and overall treatment time also are important, as are the other confounding factors described in the preceding sections.[32] Baseline pulmonary function also is highly variable among patients undergoing radiotherapy, reflecting age, smoking history, and the presence or absence of underlying cardiopulmonary disease. Because regional pulmonary fibrosis may be partially compensated by functional lung parenchyma, pretreatment lung status influences the severity of symptoms. For instance, it is well established that patients with interstitial lung disease (ILD) have a higher risk of treatment-related toxicity, in part because chemoradiotherapy can exacerbate ILD.[113,114]

These concepts, including the inherent difficulty in predicting pneumonitis, have borne out in preclinical studies despite increased homogeneity of experimental conditions. Mouse data from MD Anderson showed a clear shift in dose–response curves for changes in respiratory rate and pulmonary death as a function of the volume of lung irradiated.[35] As expected, the region of the lung irradiated was important: effects were more pronounced when the well-perfused base of the lung was irradiated, rather than the less well-perfused apex. The response to lung irradiation was quite heterogeneous, even within mice of the same age and sex, from a single highly inbred mouse strain, maintained in microbiologic isolation under rigorously controlled environmental conditions. The morbidity and symptomatology observed in individual mice was not always reflected in the histology findings found after necropsy.

Several clinical studies have attempted to predict radiotherapy-induced changes in FEV_1 by superimposing radiation treatment portals on quantitative ventilation and perfusion scans.[115–118] Unfortunately, the simple notion that the proportion of lung irradiated should match the drop in FEV_1, akin to the highly useful preoperative assessment of predicted postresection lung function, has not been verified. In fact, a report from the Massachusetts General Hospital examining global and regional pulmonary function in patients with lung cancer showed improvement in pulmonary function in 52% of patients and a mild decline in 37%; the decline was predicted from changes in radionuclide scans in only 11%.[116] Similar observations have been made in nonoperative lung cancer patients.[117] The technique of superimposing radiation treatment portals over quantitative lung perfusion scans is, therefore, of limited utility in predicting pneumonitis in individual patients. It has been suggested that the diffusing capacity is a more sensitive indicator of tolerance to radiotherapy.[115]

Unfortunately, there are no firm tests or data to guide the development of tolerable regimens of radiotherapy for patients with borderline lung function, except that we know the treatment volumes should be minimized. If the initial FEV_1 is below 1.0 L or $\mathrm{DL}_{\mathrm{CO}}$ is less than 50% of predicted, large-volume radiotherapy (e.g., elective nodal irradiation for lung cancer) may well be too hazardous. Despite its limitations, quantitative perfusion scanning in selected patients may give a worst-case scenario and help the radiation oncologist decide on dose and treatment volume. In clinical practice, radiation oncologists primarily analyze dose-volume parameters from a CT simulation scan to evaluate the risk of lung toxicity.

■ Dose-Volume Lung Effects with Fractionated Treatment

Radiation dose–volume histogram analyses derived from detailed three-dimensional treatment evaluations and applied to an empirical normal tissue complication model show only a fair correlation between volume and risk of complications.[89,119] Quantitative analysis of dose-volume parameters are further complicated by differences among studies in defining lung volumes; studies variably have included one or both lungs, have subtracted tumor volume or target volume from lung tissue, and have used different breathing techniques (i.e., breath hold versus gating in a certain phase of the breathing cycle versus average over the entire breathing cycle). Nevertheless, it is common practice to evaluate dosimetric parameters, such as V_{dose} or mean lung dose (MLD), to predict the risk of pneumonitis prospectively. The V_{dose} (i.e., $V_{20\,Gy}$ or $V_{30\,Gy}$) parameter is defined as the percentage of total volume receiving greater than the threshold dose (i.e., 20 Gy or 30 Gy, respectively). The MLD is defined as the average dose delivered to the whole lungs.

More complex dosimetric models fit observed normal tissue complication probabilities (NTCPs) to functions that include more comprehensive evaluations of low- and high-dose partial-volume organ exposures using standard radiobiologic models. Investigators at Duke[120] and the Netherlands Cancer Institute[121,122] have attempted to refine the correlation of dose–volume histograms with toxicity by factoring out nonfunctioning lung using lung perfusion scans. In patients with lung cancer, particularly those with chronic obstructive pulmonary disease (COPD), areas of hypoperfusion separate from tumor are seen frequently; irradiation of such irreversibly hypoperfused lung may not contribute additional toxicity. The existing data show a direct correlation between regional changes in ventilation, perfusion, or CT density with increasing radiation dose to that region (Fig. 57-7).[123]

These approaches may have broader applicability across various radiation treatment techniques, but they are infrequently used because of their complexity. In clinical practice, single radiation dose point metrics such as V_{20}, V_5, and MLD are used to optimize radiation treatment plans and assess the risk of a plan causing lung toxicity. From collected data in the QUANTEC effort, the risk of radiation pneumonitis is less than 20% when the MLD is less than approximately 20 Gy, when <30 to 35 Gy, or when V_5 <60%.[89] Similar estimates have been reported in a statewide prospective cohort study from Michigan, where a greater than 22% risk of pneumonitis was predicted independently by MLD >20 Gy, V20 ≥35%, and V5 ≥75%.[124] However, there is no clear dose threshold that defines safe versus unsafe doses of radiation, as dose correlates with risk of symptomatic pneumonitis in the range of lung doses that are clinically relevant. However, increasing the volume of lung of low-to-medium doses of radiation appears to have a greater impact than high doses of radiation (Table 57-3). Figure 57-8 shows the risk of

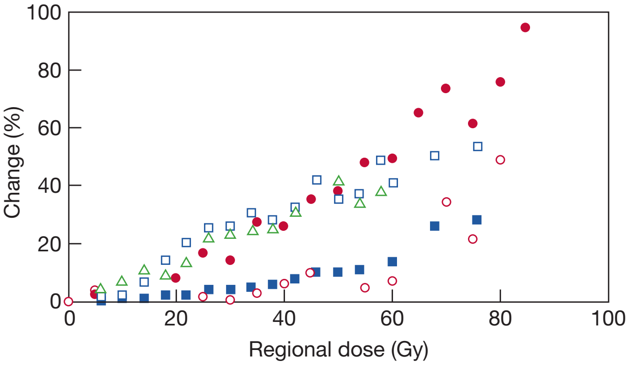

Figure 57-7 Regional changes in ventilation, perfusion, and computed tomography (CT) density from partial lung radiotherapy as a function of regional radiation dose: data from Duke University (Duke) and Netherlands Cancer Institute (NKI). V60 (per 10%)	1.00	0.98

MLD, mean lung dose.

Data from McFarlane MR, Hochstedler KA, Laucis AM, et al: Predictors of Pneumonitis After Conventionally Fractionated Radiotherapy for Locally Advanced Lung Cancer. Int J Radiat Oncol Biol Phys. 2021;111(5):1176–1185.

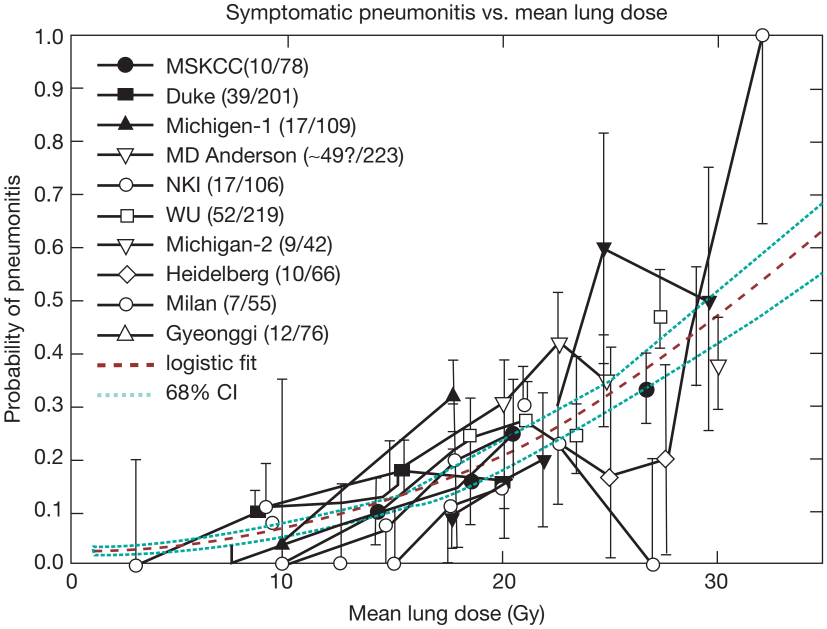

Figure 57-8 Probability of symptomatic pneumonitis versus mean lung dose; data from 10 clinical studies with *dashed line in red* fit by logistic Lyman–Kutcher–Burman dose–volume histogram model with one standard deviation shown in *light blue curves*. *(Reproduced with permission from Marks LB, Bentzen SM, Deasy JO, et al. Radiation dose-volume effects in the lung. Int J Radiat Oncol Biol Phys. 2010;76(3 Suppl):S70–S76.)*

symptomatic pulmonary complications as a function of MLD from 10 studies. These predicted risks apply to patients receiving conventional fractionation of 1.8 to 2 Gy per day and are less relevant when the dose per day is greater than 2 Gy.

In patients undergoing pneumonectomy for mesothelioma who require adjuvant radiotherapy, dosimetric parameters to avoid pneumonitis of the remaining lung are even more stringent: V_{20} should be below 4% to 10% and MLD should be below 8 Gy.[125] Hemithoracic radiation using IMRT techniques to better spare both ipsilateral and contralateral lung after pleurectomy and decortication may reduce the risk of lung toxicity. In one study of 220 patients with pleural mesothelioma after nonradical lung-sparing surgery, the incidence of grade 2+ pneumonitis was 16% when the contralateral lung was constrained to a $V_5 < 17\%$ and mean total lung dose was recommended to be under 24 Gy.[126]

■ Dose-Volume Lung Effects with SBRT

Hypofractionated treatments such as SBRT, with a high dose per fraction delivered over a reduced number of fractions, have become standard of care for inoperable early-stage lung cancer and are increasingly used in treatment of oligometastatic disease and recurrent lung cancer. Given the higher biologic effect of hypofractionated radiation, dose-volume considerations must be separated from fractionated treatments.

The authors of the normal lung-specific HyTEC effort reviewed the correlation of dosimetric factors on lung toxicity for lung SBRT.[90] In meta-analyses, mean lung dose and the V_{20} did not did not have a significant relationship with grade 2+ radiation induced lung toxicity.[127] However, multiple studies individually reported correlations between lung toxicity and mean lung dose or V_{20}. This discrepancy may be caused by differences in the definition of lung volumes, calculation of mean dose (adjusting for fraction size or not), fraction sizes, and inconsistencies in toxicity grading. Therefore, the authors advised MLD <8 Gy and $V_{20} < 10\%$ to 15% were likely to keep the risk of symptomatic lung toxicity under 10% to 15%, although there is no clear threshold tolerance level beyond which toxicity is unacceptable.

While baseline lung function has not been shown to be associated with lung toxicity after SBRT, likely due to the small volume of lung receiving high radiation dose, interstitial lung disease has been associated with an elevated risk of toxicity after SBRT.[90] For instance, in one study of 504 patients treated with SBRT to biologically effective doses between 112 and 164 Gy using an α/β ratio of 10, grade 3+ pneumonitis was noted to be 2% in patients without ILD and 32% with ILD, including 18% with grade 4+ toxicity.[128] Because of this, some radiation oncologists view ILD as a contraindication to SBRT, and at minimum physicians should strongly consider what alternative treatment options may be available for patients with ILD.

Because of the high conformality of the SBRT with small volumes of lung typically irradiated, it is feasible to treat multiple lung lesions concurrently, treat metachronous separate lung lesions, and even treat within a previously radiated area. One study of 72 patients treated with SBRT to 48 Gy in 4 fractions to an area previously overlapping a prior radiation field reported a 20.8% risk of grade 3 lung toxicity, with increased risks in patients who had poor performance status (ECOG performance score 2–3), lung function ($FEV_1 < 65\%$), and composite plan $V_{20} > 30\%$.[129] Another study demonstrated high rates of toxicity when central tumors were treated with a second course of SBRT, with grade 2+ toxicity in 8 of 11 patients, including 3 treatment-related deaths.[130]

DISEASE-SPECIFIC CONSIDERATIONS AND RISK

The risk of radiation pneumonitis is affected by the underlying malignancy being treated, as discussed below for several common disorders.

■ Lung Cancer

As most cases of pneumonitis are seen in patients treated with definitive doses of radiation therapy for lung cancer, most of the data presented above are derived from trials of lung cancer patients. Prescription doses for conventionally fractionated radiation therapy in the definitive treatment of locally advanced lung cancers typically ranges from 60 to 70 Gy in 30 to 35 fractions, preferably with concurrent chemotherapy and consolidative immunotherapy for those who are candidates. For SBRT, treatment regimens generally deliver higher doses per fraction over 1 to 5 fractions for peripheral tumors. More moderately hypofractionated courses should be considered for central lung tumors, where the risk of severe toxicities limits the safety of shorter regimens. In most series of patients receiving definitive conventionally fractionated thoracic radiotherapy, the risk of symptomatic radiation pneumonitis is usually about 10% to 20%, and some degree of radiographic fibrosis is almost universal. For SBRT, the volume of lung irradiated is typically reduced, and similarly symptomatic pneumonitis rates are lower, in the range of 5% to 15%.[89]

In clinical trials that have escalated radiation doses to the tumor (and small amount of surrounding lung) there has not been a significant increase in lung toxicity, likely because the number of nonfunctional alveoli is not greatly increased by this increase in dose.[131] In the RTOG 0617 trial, dose escalation from 60 to 74 Gy did not lead to greater grade 3+ pneumonitis rates (4% and 7%, respectively).[132] The cohorts treated with 74 Gy had decreased overall survival compared with those treated with 60 Gy, which some have hypothesized is due to increased radiation dose to the heart and esophagus.[133] Importantly, on secondary analysis patients treated with IMRT (47%) had a reduced risk of grade 3 pneumonitis compared to 3D-conformal radiotherapy (3.5% vs. 7.9%), and higher lung V20 was associated with increased pneumonitis risk.[134]

■ Esophageal Cancer

Radiation therapy plays a role in treatment for most patients who have locoregional esophageal cancers, outside of those with select T1 tumors. Radiation doses delivered are typically in the range of 41.4 to 50.4 Gy, often combined with concurrent chemotherapy for those who are medically fit to tolerate treatment. With the central location of the esophagus in the thorax, a significant amount of lung is frequently exposed to low doses of radiation, especially with IMRT. Rates of grade 3 or greater pneumonitis are typically under 5% for chemoradiation alone.[135] In patients treated with a trimodality approach, the timing of chemoradiation prior to surgery may lead to pulmonary toxicity post-operatively.[136] Proton beam therapy can be used to reduce radiation doses to the heart and lung, and to potentially reduce cardiopulmonary toxicities in turn. In a randomized phase 2 trial comparing 50.4 Gy of preoperative chemoradiation delivered with IMRT versus proton beam therapy, the novel endpoint called “total toxicity burden” was reduced with proton treatment.[137] Symptomatic radiation pneumonitis made up only a small portion of toxicities, with 3 of 72 patients treated with IMRT having grade 2 pneumonitis compared with 1 of 73 patients with proton beam therapy. However, the reduction in radiation dose to the heart and lung with protons also correlated with reduction in other pulmonary toxicities, including ARDS, pleural effusion, pneumonia, and need for re-intubation.

■ Breast Cancer

Breast cancer radiotherapy, whether after lumpectomy or after mastectomy, typically uses opposed tangential beams that irradiate a volume of lung anterolateral to a plane demarcating the midchest to the lateral axillary line. Standard fractionation to a dose of approximately 50 Gy in 25 fractions is recommended in some scenarios, and hypofractionation with approximately 40 to 42.5 Gy in 15 to 16 fractions or even shorter regimens in 5 fractions may be used in other scenarios. The volume of the ipsilateral lung irradiated can be estimated for individual patients from the simulator films and is typically about 20% of the ipsilateral lung volume. If the supraclavicular and axillary nodes are irradiated as well, the anterior treatment portals are matched to the tangential chest wall fields. As a result, the apex of the lung (roughly another 10%–15% of ipsilateral lung volume) also is irradiated. The incidence of symptomatic pneumonitis from tangential fields alone is roughly 0.5%, with some series documenting an increased risk with increasing lung volume.[59,138] It is desirable to keep the irradiated volume below approximately 25%, if possible. Nodal irradiation increases the risk for pneumonitis to 0.5% to 1.5%. Risk further increases to as high as 9% when chemotherapy is given concurrently. The risk of pneumonitis is much lower when chemotherapy and radiation are given sequentially.[59,138]

Techniques such as deep inspiration breath holding (DIBH) are frequently used to reduce the radiation dose to the heart and lungs in patients treated for breast cancer. The utility of this technique is demonstrated in Fig. 57-9. Figure 57-9A demonstrates the radiation treatment plan of a patient treated with 40 Gy in 15 fractions using DIBH technique. Figure 57-9B shows the same patient’s scan at the same axial level when the patient was breathing freely, with contours of the body, lungs, and heart in DIBH overlayed. In comparison with the DIBH technique, greater proportions of the heart and lung would be exposed to radiation.

■ Early-stage Hodgkin Disease

Radiotherapy for early-stage Hodgkin lymphoma, using moderate doses (40–45 Gy in 1.5- to 2-Gy fractions) and large volumes to treat lymph node-bearing regions, represented a remarkable success story in oncology. Because it produced very high cure rates in a young patient population, allowing for extended follow-up over several decades, this experience has also produced considerable data regarding late radiation toxicities.[139] In part due to these toxicities, the treatment paradigm has shifted toward combination chemotherapy and lower-dose/smaller-field radiation.

With the protocols that were historically employed, the chest is irradiated with treatment portals, generically called “mantle fields,”

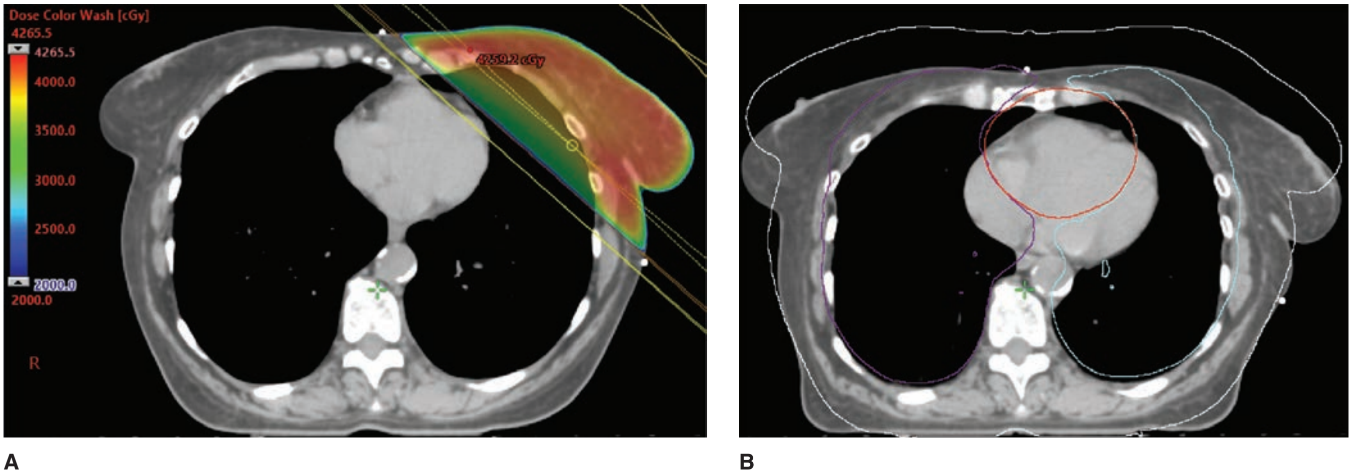

Figure 57-9 A 61-year-old woman with stage IA left sided breast cancer was treated with adjuvant radiation therapy to 40.05 Gy in 15 fractions to reduce the risk of recurrence. **A.** The radiation plan, which utilizes two opposed tangent beams matched posteriorly, is overlayed on her CT simulation scan, with doses above 20 Gy shown in color wash. The orange line next to the color wash represents the beam edge. Deep-inspiration-breath-hold (DIBH) technique was used to reduce heart dose. DIBH technique also reduces lung doses, but of note in this patient radiation dose to the lung is acceptable even without DIBH. **B.** The same patient also underwent CT simulation scan in free-breathing, which is displayed for comparison. Contours of the body (white), left lung (blue), right lung (purple), and heart (red) in the DIBH scan are drawn and demonstrate the increase in lung volumes seen with DIBH.

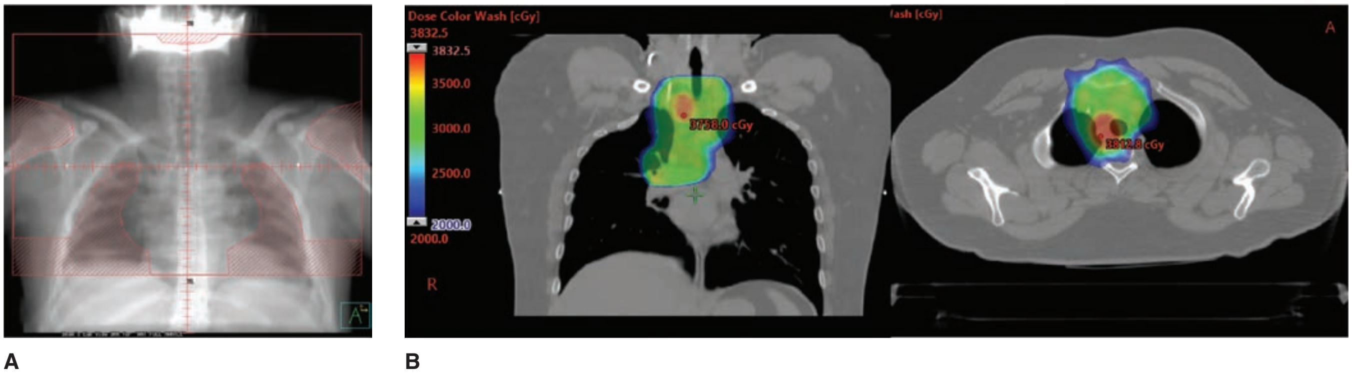

Figure 57-10 **A.** An example of a mantle radiation field shows broad inclusion of the lymph node regions above the diaphragm, with blocking of the lung and humeral head. **B.** In comparison, involved site radiation therapy only targets the specific location of disease. In this example, coronal and axial images are depicted of a treatment plan for a patient with Hodgkin's lymphoma involving the mediastinum, including a right paratracheal lymph node that did not have a complete response to chemotherapy. Involved site radiation depends on systemic therapy to treat subclinical disease in areas adjacent to the gross disease given the reduction in treatment volumes.

as depicted in Fig. 57-10A. With updated radiation techniques that used sequential shrinking fields, such as involved site radiotherapy (Fig. 57-10B), the incidence of symptomatic radiation pneumonitis was reduced to 3% to 4%.[140] The risk of pneumonitis was roughly 10% when full doses of both chemotherapy and radiation to a mantle field are given sequentially, even when bleomycin is not part of the regimen.

Studies on pulmonary function in patients with Hodgkin disease suggest that a transient reduction in FEV_1 and vital capacity, on the order of 5% to 20%, occurs 3 to 9 months after radiotherapy, corresponding to the period of pneumonitis.[141] There tends to be some recovery by about 1 year. Late follow-up of pulmonary function in patients with Hodgkin disease further suggests that mantle field radiotherapy is associated with small, and, for the most part, clinically insignificant, reductions in vital capacity and DL_{CO}.[139] These decreases in pulmonary function tests were associated with minor, if any, symptomatology, even for treatment regimens that included sequential chemotherapy with doxorubicin or bleomycin.

Primary radiotherapy for Hodgkin disease is now rarely practiced. Decades of follow-up in patients cured of their lymphomas show a steady increase in secondary cancers as well as cardiac complications. As a consequence, clinical trials have shown improved disease-free survival over 5 to 10 years with primary chemotherapy. Furthermore, rather than the larger volumes previously irradiated with mantle-field or involved-field radiation, improvements in imaging and treatment planning have allowed reduction of the treatment target volume to only the initially involved site of disease. In this setting, in which lower-dose (20–30 Gy) radiotherapy after chemotherapy is often delivered, the incidence of clinical pneumonitis is quite low. Longer-term follow-up of toxicities from combined-modality therapy in Hodgkin disease is in progress.

FUTURE DIRECTIONS

With improvements in technology, our understanding of the prediction and mitigation of radiation pneumonitis has improved significantly in the last several decades, and multiple new innovations are currently being pursued. Broadly speaking, reducing the risk of pneumonitis can be done by limiting radiation fields, improving patient selection and individual dose tolerance, or widening the therapeutic ratio through biologic innovations.

■ Improvements in the Accuracy and Precision of RT

Evolving radiation technologies have transformed the field over the last several decades. There should continue to be improvement in technologies that allow delivery of more conformal treatments, which may further reduce radiation toxicities for normal tissue. IMRT and volumetric arc therapy, which deliver radiation beams of varying intensity across multiple beams (or an infinite number of beam angles in the case of arc therapies) are now standard techniques in the radiotherapy clinic. Furthermore, daily image-guided radiation therapy is now standard of care, using CT or x-ray images obtained at the time of treatment to ensure that the patient has been set up properly.

Proton therapy is an evolving radiation treatment modality with expanding indications and improving accessibility. As discussed above, proton therapy offers a dosimetric advantage over photon radiotherapy due to the deposition of the majority of a proton's energy at the end of its path (resulting in the "Bragg peak"), and the sparing of dose to tissue beyond this point. Proton therapy has clear benefits in reducing radiation dose to organs-at-risk including the lungs, and in particular has generated excitement for thoracic targets outside of the lung, such as the esophagus or the mediastinum (e.g., mediastinal Hodgkin lymphoma). However, risks of pneumonitis for these patients are lower than when treating lung cancer, and the primary benefit of radiation is in reducing other treatment-related morbidities. In lung cancer, the role of proton therapy is not yet established but continues to be explored. A randomized trial at MD Anderson Cancer Center comparing IMRT to proton therapy (using the older technique of passive scatter rather than pencil beam scanning) for locally advanced NSCLC showed no difference in grade 3 radiation pneumonitis (protons 10.5% vs. IMRT 6.5%).[142] However, the authors noted that a large learning curve for proton treatment planning and delivery led to a decrease in symptomatic pneumonitis risk from 31% to 13% between the first and second halves of the study, demonstrating the promise of continued development of and experience with proton therapy.

Because lung tumors move significantly with respiratory motion, large margins were needed to ensure that a tumor was being appropriately treated. However, improvements in respiratory motion management have allowed for reduction in the margins needed from a lung tumor, and therefore reduction in normal lung dose targeted. Four-dimensional computed tomography (4D-CT) is now routinely used when performing CT simulation near the thorax and allows for visualization and accounting of a tumor's movement throughout a normal respiratory cycle. Reduction of treatment volumes can also be achieved by only treating during a certain part of the respiratory cycle. Known as respiratory gating, this can be performed by only delivering radiation when the tumor passes through a certain location or by using breath-hold techniques, in which a patient holds their breath at a particular point of the respiratory cycle during treatment. This requires real-time monitoring of the chest wall for respiratory motion, or the tumor itself. Real-time adaptive radiotherapy using MRI has been performed and shown to be feasible, although it is not widely available across radiation oncology centers.[143,144] Similarly, technologies that utilize real-time positron emission tomography to deliver radiation only to the current location of a tumor have been developed and are currently being clinically tested.[145]

Improvements in Patient Selection and Dose Reduction

With years of data from clinical trials, retrospective analyses, and animal studies, radiation oncologists today utilize the dose–volume parameters derived from an individual patient's anatomy, as well as the clinical risk factors in the patient's history, to estimate the risk of adverse events and weigh this against the probability of tumor control. However, a great amount of data is potentially available and unutilized in the prediction of radiation-induced lung injury, and ultimate optimization of an individual patient's treatment plan. For instance, studies of genetic predictors of radiation therapy have yielded multiple genetic risk factors including single-nucleotide polymorphisms in MTHFR,[46] ATM,[47] TGB-β1,[146] and HSPB1.[147] These associations are not strong enough on their own to guide dose modification. Future advances in computation and genetic sequencing may yield models accurate enough for the oncologist to utilize.

Additionally, advances in machine learning may allow for improved radiation pneumonitis modeling. Multiple different machine learning classification algorithms including random forest, support vector machines, and neural networks have been employed to analyze large amounts of clinical variables and model the risk of pneumonitis after treatment of lung cancer.[149] Radiomic prediction models on pretreatment CT scans have demonstrated some ability to predict outcomes in lung cancer patients including radiation pneumonitis.[150] Newer machine learning techniques such as deep learning, which utilizes layers of artificial neural networks to analyze data, have shown great potential in their ability to predict patient outcomes, and could potentially be utilized in the clinic to aid treatment decisions.

Ideally, machine learning and big data would form the basis of decision support tools that could be integrated into the clinic to aid personalized treatment decisions. While there is an enormous amount of data stored in electronic medical systems across the world, a lack of standardization in how data is collected and encoded complicates its full utilization. The ability to combine data across multiple health centers while also maintaining patient privacy will be critical in this endeavor.

Targeted Drugs and Biologic Innovations

Widening the therapeutic ratio by preferentially radiosensitizing tumor or protecting normal tissue from radiation with small molecules is an ongoing area of investigation, but attempts to reduce the risk of radiation pulmonary toxicity with systemic agents have thus far proved mostly unsuccessful. For instance, amifostine has been examined extensively because of its limited distribution into tumors and activity as a free radical scavenger, which results in a decrease in radiation cytotoxicity. Several small phase 3 trials in lung cancer suggested a benefit to amifostine during thoracic radiotherapy, with a decrease not only in pneumonitis, but also in radiation esophagitis as well.[150] However, a larger multi-institutional trial, RTOG 98-01, failed to document a difference in pneumonitis rates with amifostine,[151] and guidelines do not recommend its use for prevention of radiation toxicities. In a small trial of 40 patients randomized to pentoxifylline or placebo during radiotherapy for breast or lung cancer, there were significantly fewer patients in the pentoxifylline group that had grade 2 or 3 pulmonary toxicity (20% vs. 50%) and improvements in D_{LCO} with pentoxifylline, but this has yet to be reproduced in a larger cohort.[152] The angiotensin-converting enzyme (ACE) inhibitor captopril was shown to decrease radiation-induced pulmonary fibrosis in animal studies,[153,154] and retrospective series have shown a decrease in radiation pneumonitis associated with the incidental use of ACE inhibitors.[155,156] However, a randomized trial designed to test whether captopril mitigates radiation-induced pulmonary toxicity was unable to adequately accrue.[157]

Therapies that preferentially radiosensitize tumors have the potential to reduce the pneumonitis if the radiosensitizer allows radiation dose to be reduced. Several targeted agents like PARP inhibitors can sensitize thoracic tumors to radiation therapy, and clinical trials evaluating the use of these are ongoing. Caution should be exercised, however, as radiosensitizers may also sensitize normal tissue and increase risk of radiation pneumonitis, as has been seen with bevacizumab.[158]

FLASH radiotherapy has also generated recent excitement due to a potential to spare normal tissues from toxicity. This technique delivers radiation using extremely high dose rates, exceeding 40 Gy/s, and has been shown to preferentially spare normal tissue in animal studies, potentially due to rapid depletion of oxygen.[159] In mice treated with doses up to 30 Gy using FLASH or conventional dose rates, pulmonary fibrosis was found in 100% of animals irradiated with conventional dose rates and none with FLASH below 20 Gy.[160] Meanwhile, treatment efficacy against orthotopic lung tumors was similar between the two dose rates. A better understanding of the biological effects of FLASH and the technical challenges for its delivery will be required prior to human studies. Ultimately, well-designed, thoughtful clinical trials are necessary to establish the benefit of these potential innovations.

CHAPTER 58

Pulmonary Manifestations of the Collagen Vascular Diseases

Kevin P. Toole
Gregory P. Cosgrove

INTRODUCTION

Pleuropulmonary involvement associated with the collagen vascular diseases occurs frequently. All the structures within the respiratory tract may be affected, either separately or in combination. This includes the respiratory muscles, the pleura, the conducting airways, and the lung parenchyma—the small airways, the interstitium, or the pulmonary vessels. Patients with underlying collagen vascular disease experience an increased incidence of community-acquired pneumonia, as well as pneumonia associated with the immunosuppressive drugs employed for treatment. Anti–tumor necrosis factor α (anti–TNF-α) agents increase the risk for infections, particularly typical and atypical mycobacterial pathogens (e.g., tuberculous and nontuberculous), *Pneumocystis jirovecii*, and *Nocardia* species. Cytotoxic drugs, particularly methotrexate and gold, also can induce various noninfectious interstitial reactions, which are often difficult to distinguish from a primary interstitial complication of a collagen vascular disease.[1]

Although most pulmonary complications appear in an established case of a collagen vascular disease, lung disease may precede the more typical systemic manifestations.[2] For example, in both rheumatoid arthritis and polymyositis–dermatomyositis, the interstitial lung disease may precede the joint and muscle disease by several months to several years. This is also the case, but to a lesser extent, for scleroderma. In one study, 19% of patients initially diagnosed with idiopathic pulmonary fibrosis developed a collagen vascular disease over a period of 1 to 11 years, primarily rheumatoid arthritis or polymyositis–dermatomyositis. These individuals were younger and more likely to be women. Pleuritis with or without effusion sometimes heralds the onset of rheumatoid arthritis or systemic lupus erythematosus (SLE). An acute immunologic pneumonitis or diffuse alveolar hemorrhage has been reported to be the initial disease manifestation in SLE, polymyositis–dermatomyositis, and mixed connective-tissue disease.

The incidence of the pleuropulmonary complications (Table 58-1) is variable. Interstitial lung disease is reported to be as high as 60% in premortem and 100% in postmortem studies in systemic sclerosis. In contrast, interstitial lung disease in ankylosing spondylitis is an uncommon event. In general, the incidence of interstitial lung disease is increasing for most of the collagen vascular diseases, primarily due to increased recognition and more sensitive screening techniques such as high-resolution computed tomography (HRCT) and bronchoalveolar lavage (BAL), which will detect abnormalities in both asymptomatic as well as symptomatic patients with normal chest radiographs. Prior studies assessing the incidence of disease relied on physiologic testing, which included spirometry, lung volumes, and diffusing capacity but did not measure rest and exercise gas exchange, which is the most sensitive physiologic marker of interstitial lung disease and pulmonary vascular disease.

TABLE 58-1 Pulmonary Complications of the Collagen Vascular Diseases

	Relative Frequency (0–4)						
Manifestation	SLE	RA	SS	PM-DM	MCTD	AS	Sjögren
Respiratory muscle dysfunction	2	1	0	2	1	0	0
Aspiration pneumonia	0	0	3	3	2	0	2
Primary pulmonary hypertension	2	1	4	1	2	0	0
Vasculitis	2	2	0	1	1	0	0

Usual interstitial pneumonitis	2	3	2	2	2	1	1
Honeycomb lung	1	2	4	3	2	1	1
Bronchiolitis obliterans organizing pneumonia	1	3	1	3	2	0	1
Bronchiolitis	1	2	1	0	1	0	1
Obliterative bronchiolitis	0	2	0	0	0	0	1
Pleural effusion	2	3	1	0	2	0	1
Parenchymal nodules	0	2	0	0	0	0	1

SLE, systemic lupus erythematosus; RA, rheumatoid arthritis; SS, systemic sclerosis (scleroderma); PM-DM, polymyositis-dermatomyositis; MCTD, mixed connective-tissue disease; AS, ankylosing spondylitis; Sjögren, Sjögren syndrome; DAH, diffuse alveolar hemorrhage.

PULMONARY PARENCHYMAL, VASCULAR, AND AIRWAY PATHOLOGY IN THE COLLAGEN VASCULAR DISEASES

The spectrum of pathologic changes in the lung parenchyma, pulmonary vasculature, and airways are considered below, prior to a discussion of clinical findings in individual collagen vascular diseases.

■ Interstitial Lung Disease

Interstitial involvement is a common manifestation of the collagen vascular disorders, presenting with a number of different inflammatory responses within the lung. Each response may represent a different form of lung injury or response to injury. Defining which response is underlying a patient's interstitial lung disease has important prognostic and therapeutic significance.

Diffuse alveolar damage (DAD) is the underlying histologic lesion that is also seen in the acute respiratory distress syndrome, idiopathic acute interstitial pneumonitis (Hamman–Rich syndrome), severe viral pneumonias, and cytotoxicity from some drugs. This damage consists of a mixed interstitial inflammatory infiltrate, interstitial edema and fibrin deposition, and characteristic intra-alveolar hyaline membrane formation. Intra-alveolar red blood cells (diffuse alveolar hemorrhage) may be present in severe cases. With progression, there is intra-alveolar organization, intra-alveolar and interstitial fibrosis, alveolar collapse, and the development of an end-stage fibrotic or "honeycomb" lung. An acute immunologic pneumonia, seen in SLE (acute lupus pneumonitis) and in polymyositis–dermatomyositis, may also demonstrate this underlying histologic appearance.

Nonspecific interstitial pneumonitis (NSIP) refers to a spectrum of histologic features with varying degrees of lymphoplasmacytic infiltration of the interstitium and collagen deposition (Fig. 58-1). In the cellular form, lymphoplasmacytic interstitial inflammation exists with associated type II alveolar epithelial cell hyperplasia. In the fibrosing form, the inflammation is accompanied by a temporally and spatially homogeneous deposition of collagen (fibrosis). Architectural distortion or honeycombing may occur in advanced cases, and the presence of fibrosis dramatically changes the clinical course and prognosis to one resembling that seen in usual interstitial pneumonitis (UIP) (see below). NSIP is most frequently seen in patients with rheumatoid arthritis, polymyositis–dermatomyositis, mixed connective-tissue disease, and scleroderma.

Lymphocytic interstitial pneumonitis refers to a monotonous infiltration of the interstitium by mature lymphocytes (Fig. 58-2). These lymphocytes tend to form germinal centers within the interstitium and to display an angiocentric distribution. Other features of lymphocytic interstitial pneumonia include macrophagic giant cells, granuloma formation, and amyloid deposition. Lymphocytic interstitial pneumonitis can progress to UIP and end-stage honeycomb lung. Among the collagen vascular diseases, this pneumonitis most commonly accompanies the primary form of Sjögren syndrome and, to a lesser extent, the secondary form of Sjögren syndrome appearing with other collagen vascular diseases, particularly rheumatoid arthritis.

Usual interstitial pneumonitis (UIP) is the pathologic lesion of idiopathic pulmonary fibrosis and can also appear in all the collagen vascular diseases. It consists of varying degrees of mononuclear cell infiltration and fibroblastic proliferation leading to collagen deposition within the alveolar interstitium (Fig. 58-3). With progression, this fibrotic reaction results in marked distortion of the lung architecture; what remains are 2- to 3-mm cystic spaces lined by metaplastic epithelium, the so-called honeycomb lung (Fig. 58-4). Other features of UIP include type II epithelial cell hyperplasia producing a "hob-nailed" appearance on the alveolar surface, collections of intra-alveolar macrophages, and smooth-muscle proliferation within the interstitium. Additional abnormalities seen in collagen vascular disease–associated UIP, but not in patients with idiopathic pulmonary fibrosis, may include focal chronic pleuritis, lymphoid follicles with germinal center formation, perivascular collagen deposition, and an increase in CD4+ T lymphocytes, especially in rheumatoid arthritis.

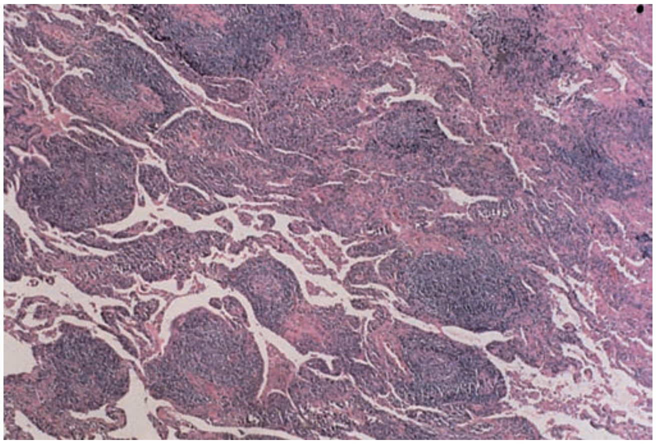

Figure 58-2 Lymphocytic interstitial pneumonitis in a patient with primary Sjögren syndrome. There is a dense lymphocytic infiltrate, broadening the interstitium and lymphoid follicles.

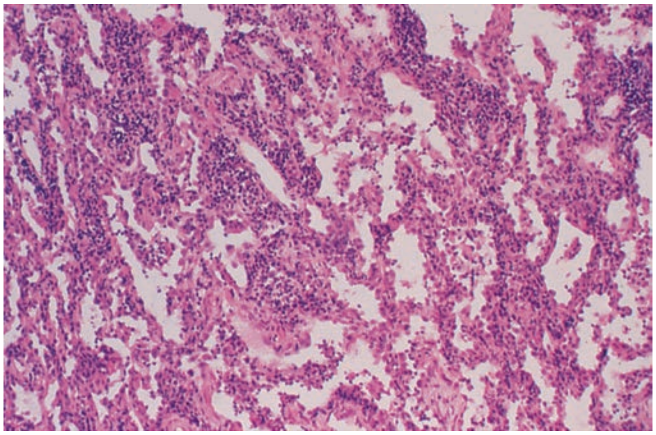

Figure 58-1 Nonspecific interstitial pneumonitis (NSIP) in rheumatoid arthritis. There is a lymphoplasmacytic infiltration of the interstitial compartment with minimal collagen deposition.

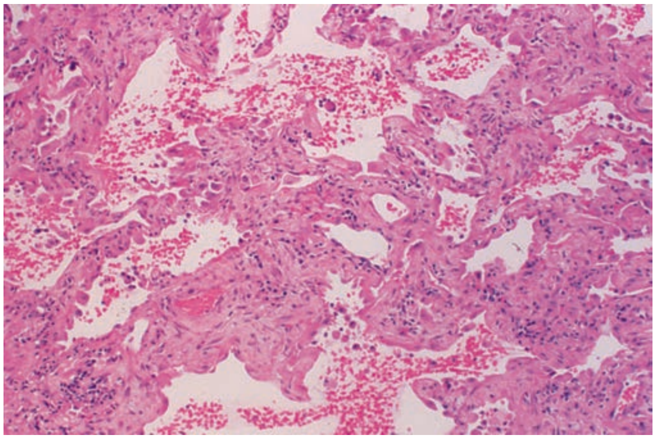

Figure 58-3 Usual interstitial pneumonia (UIP) in a patient with rheumatoid arthritis. There is broadening of the interstitium by varying degrees of mononuclear cell infiltration and collagen deposition.

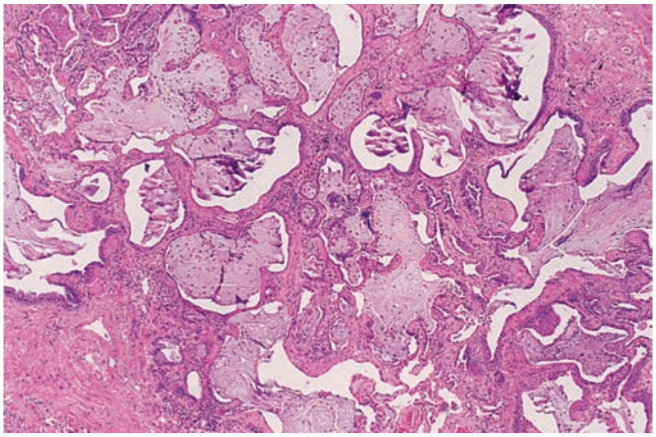

Figure 58-4 Advanced UIP in a patient with scleroderma (honeycomb lung). Normal alveolar tissue is replaced with broad bands of fibrous tissue lined by metaplastic epithelium and filled with inspissated mucus, producing a cyst-like network. *(Reproduced with permission from the Armed Forces Institute of Pathology [AFIP].)*

Organizing pneumonia, previously termed *bronchiolitis obliterans organizing pneumonia*, is a distinctive histologic lesion that follows a variety of insults to the alveolar structures including drugs, infection, radiation, and an idiopathic variety. Organizing pneumonia can also complicate the collagen vascular diseases, particularly rheumatoid arthritis and polymyositis–dermatomyositis. Three features constitute the histologic picture: (1) intra-alveolar space and intra-alveolar ductal fibroblastic proliferation with early collagen deposition (Masson bodies), (2) inflammatory polyps consisting of fibroblasts and mononuclear cells protruding into the lumens of respiratory and terminal bronchioles, and (3) alveolar septal lymphoplasmacytic infiltrate with type II pneumocyte hyperplasia within affected areas (Fig. 58-5). Organizing pneumonia has the potential for being a completely reversible lesion; however, with continuing injury it may progress to end-stage fibrosis and honeycomb lung.

■ Pulmonary Vascular Disease

A form of pulmonary artery hypertension, which most commonly appears in patients with scleroderma and is now being increasingly recognized in SLE, rheumatoid arthritis, and mixed connective-tissue disease, is histologically identical to the syndrome of idiopathic pulmonary artery hypertension (IPAH) seen in young women without collagen vascular disease, formerly known as primary pulmonary hypertension. Idiopathic and PAH associated with an underlying connective tissue disease are classified and grouped in Pulmonary Hypertension (PH) World Health Organization (WHO) Group 1 due to their similarities in pathophysiology, clinical presentation, and therapeutic options.[3] In patients with SLE and the antiphospholipid syndrome, pulmonary artery hypertension may also develop (WHO PH Group 4) due to chronic thromboembolic events and pulmonary artery obstruction.[4]

Vasculitis refers to an acute inflammatory angiodestructive process resulting in fibrinoid necrosis of the vascular wall. In the collagen vascular diseases, this is most often a small-vessel vasculitis involving arterioles and small muscular pulmonary arteries. Although uncommon, this is seen with greatest regularity in SLE and less frequently in rheumatoid arthritis, polymyositis–dermatomyositis, and mixed connective-tissue disease. Often accompanying the arteriolitis is the lesion of pulmonary capillaritis (see below).

■ Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage is recognized by the accumulation of red blood cells within the alveolar spaces, and with recurrent episodes, intra-alveolar and interstitial hemosiderin is deposited, and fibrosis may result. There are two different histologic subtypes seen in diffuse alveolar hemorrhage. One is devoid of inflammation and is referred to as *bland hemorrhage* (Fig. 58-6). It is therefore similar in histologic appearance to idiopathic pulmonary hemosiderosis. The other, pulmonary capillaritis, is a unique neutrophilic infiltration of the alveolar interstitium, which results in necrosis and loss of integrity of the alveolar–capillary basement membrane, capillary destruction and thrombosis, and a leakage of red blood cells into the alveolar space (Fig. 58-7). A unique feature in pulmonary capillaritis is that many of the infiltrating neutrophils are undergoing fragmentation (leukocytoclasis), and others appear as densely staining apoptotic cells. Nuclear debris ("dust") subsequently accumulates within the necrotic, edematous interstitium, and intra-alveolar compartments while red blood cells freely leak into the interstitial matrix due to capillary destruction. Capillary and arteriolar thrombosis, organizing pneumonia, and type II epithelial cell hyperplasia also may be seen.

Capillaritis is most commonly seen in the systemic vasculitides, particularly granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) and microscopic polyangiitis (MPA),

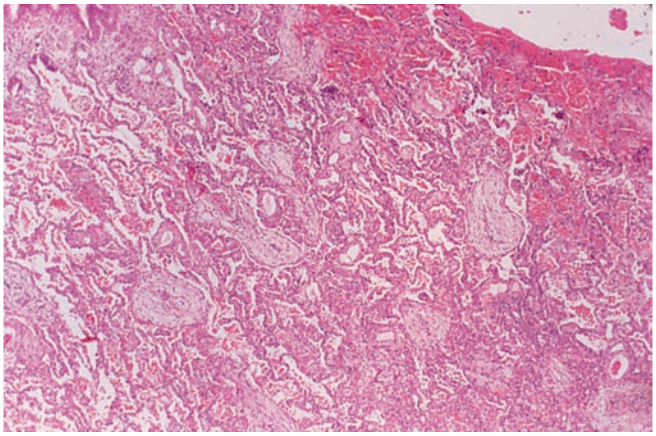

Figure 58-5 Bronchiolitis obliterans organizing pneumonia in a patient with rheumatoid arthritis. There is a mononuclear cellular infiltration of the interstitium without collagen deposition as well as alveolar duct and intra-alveolar fibroblastic proliferation and early collagen production.

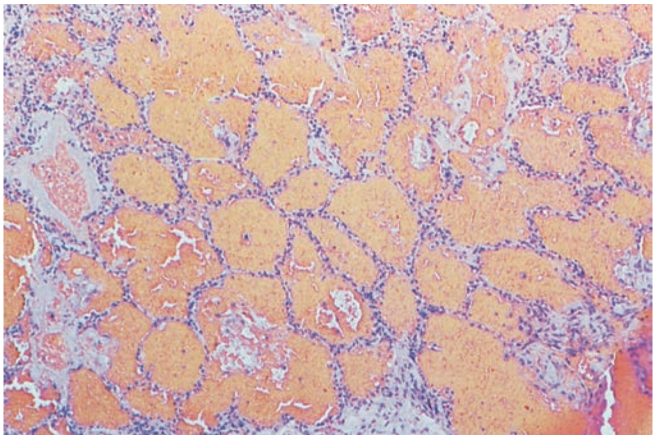

Figure 58-6 Bland diffuse alveolar hemorrhage in SLE. There is little if any interstitial reaction except for type II pneumocyte epithelial cell hyperplasia. The alveolar spaces are filled with red blood cells.

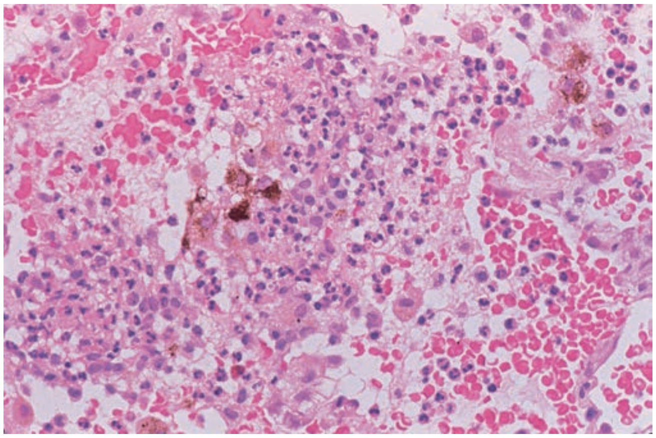

Figure 58-7 Low-power view of pulmonary capillaritis in a patient with SLE. There is marked thickening of the interstitial compartment and infiltration by acute and chronic inflammatory cells. The alveolar spaces are filled with red blood cells and neutrophils.

the small-vessel variant of polyarteritis nodosa. Of the collagen vascular diseases, both bland pulmonary hemorrhage and diffuse alveolar hemorrhage secondary to pulmonary capillaritis appear most commonly in SLE. Cases of pulmonary capillaritis have also been reported to occur in rheumatoid arthritis, Sjögren syndrome, polymyositis–dermatomyositis, and mixed connective-tissue disease.

■ Bronchiolitis

Bronchiolitis refers to an inflammatory-fibrotic process involving the terminal and respiratory bronchioles and possibly the surrounding alveolar structures. Respiratory bronchiolitis is primarily seen in smokers with or without an associated collagen vascular disease. There is also a primary form of cellular bronchiolitis that complicates the collagen vascular diseases, most often appearing in rheumatoid arthritis and Sjögren syndrome. Histologically, there is a mononuclear cell infiltration of the wall of the bronchiole without impingement of the bronchiolar lumen. In contrast, in bronchiolitis obliterans, or obliterative bronchiolitis, there is a concentric fibrous obliteration of the bronchiolar lumen leading to a severe obstructive lung disease (Fig. 58-8). Bronchiolitis obliterans is most often reported as a complication of rheumatoid arthritis.

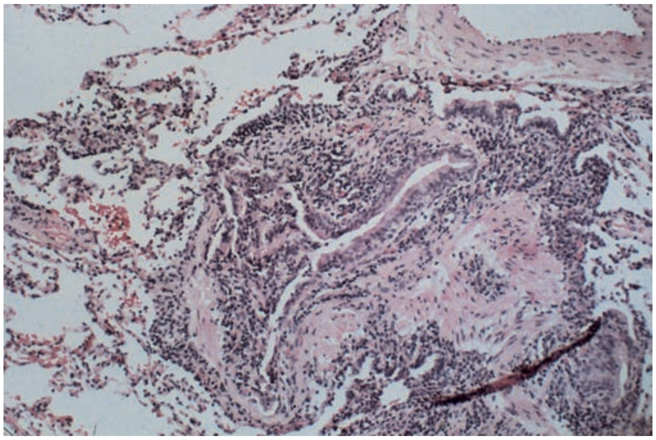

Figure 58-8 Obliterative bronchiolitis in rheumatoid arthritis. There is a marked reduction of the luminal diameter due to concentric fibrous obliteration and dense chronic inflammation. *(Reproduced with permission from Schwarz MI, Lynch DA, Tuder R. Bronchiolitis obliterans: The lone manifestation of rheumatoid arthritis. Eur Respir J. 1994;7(4):817–820.)*

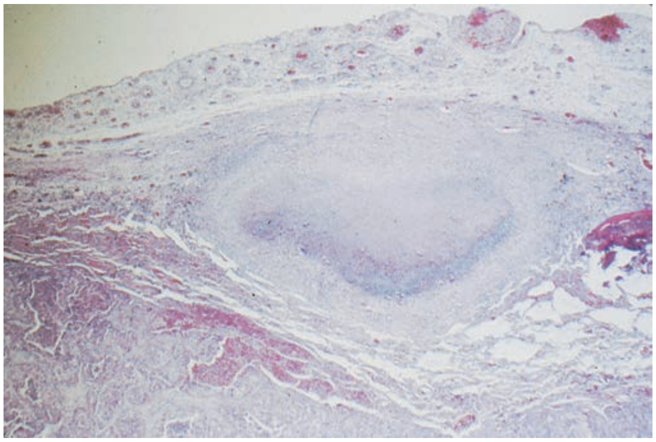

Figure 58-9 Typical subpleural location of a necrobiotic rheumatoid nodule. There is a central area of fibrinoid debris surrounded by palisading histiocytes.

■ Parenchymal Nodules

Noninfectious inflammatory parenchymal nodules occur in both rheumatoid arthritis and Sjögren's syndrome. In rheumatoid arthritis the nodules are referred to as the *necrobiotic* or *rheumatoid nodules*. These lesions are found both in the pleura and lung parenchyma and are identical in appearance to a subcutaneous rheumatoid nodule. In the lung parenchyma, these nodules are located in the interlobular septa and in the subpleural parenchyma. The necrobiotic nodule is comprised of palisading histiocytes, giant cells, and other mononuclear cells surrounding an area of fibrinoid debris (Fig. 58-9). In Sjögren syndrome, a rounded lesion known as pseudolymphoma can occasionally be detected on the chest radiograph. Pseudolymphoma is considered a localized form of lymphocytic interstitial pneumonia and is made up of a dense infiltrate of lymphocytes and histiocytes with occasional granuloma formation. There is a potential risk for malignant transformation in pseudolymphoma as well as in the other forms of lymphocytic interstitial pneumonia.

SYSTEMIC LUPUS ERYTHEMATOSUS: CLINICAL FEATURES

SLE is characterized by the production of antibodies against various cellular antigens derived from the nucleus, cytoplasm, or cell membrane. Tissue injury appears to be associated with the development of immune complexes, the presence of low serum complement levels, and the production of antibodies to native DNA. Pleuropulmonary involvement in SLE occurs in the vast majority of patients (97.8%), with pleuritis (77%), bacterial infections (58%), and diffuse alveolar hemorrhage (26%) being the most common.[5,6] Lung injury is thought to be the result of an immune complex–mediated injury and appears to increase in incidence depending on the age of the patient, duration of illness, pleuritis, and the presence of specific autoantibodies. Pulmonary vascular and shrinking lung syndrome appear to be associated with the development of the anti-RNP autoantibody.[7] A number of syndromes (Table 58-2) are associated with acute respiratory-type illness in SLE. Patients with SLE who present with a febrile illness, cough with or without productive sputum, and new pulmonary infiltrates must be considered to have an infectious pneumonia, although acute lupus pneumonitis and diffuse alveolar hemorrhage may have a similar presentation.[8] Infection can be community-acquired or a complication of immunosuppressive therapy. Infectious pneumonia represents the most common cause of pulmonary disease in SLE, and infections in

TABLE 58-2 Acute Lung Syndromes in Systemic Lupus Erythematosus

general represent the most common reason for death (33%–77%).[9] Bronchoalveolar lavage is often helpful in excluding an infectious pneumonia in the immunocompromised SLE patient.

Another important consideration in an acutely dyspneic patient with SLE is pulmonary embolism, a complication reportedly occurring in up to 25% of patients and a significant cause of mortality.[10] The occurrence of thromboembolic disease correlates with the presence in the serum of acquired antiphospholipid antibodies (lupus anticoagulant or anticardiolipin).[11] The most common epitope(s) to which antibodies exist in these patients is β_2-glycoprotein I. A more appropriate term may therefore be anti–β_2-glycoprotein syndrome. Up to a third of patients with SLE have the antiphospholipid syndrome. Thrombocytopenia, recurrent venous or arterial thrombosis, hemolytic anemia, leg ulcers, and recurrent fetal loss are also manifestations of antiphospholipid syndrome.

Other causes for acute respiratory failure in patients with SLE include a volume overload state, due either to renal failure or to congestive heart failure secondary to myocarditis. Uremic pneumonitis with underlying DAD is also a possible cause of an acutely dyspneic SLE patient with renal failure. A syndrome, *acute reversible hypoxemia*, occurring in acutely ill SLE patients who are experiencing systemic exacerbations has been described.[12] These patients have hypoxemia and a widened alveolar–arterial oxygen gradient, but both the chest radiograph and ventilation–perfusion lung scans are normal. It is postulated that there is complement-activated neutrophil aggregation in the pulmonary vasculature. The hypoxemia improves with immunosuppressive therapy. Given the high incidence of antiphospholipid syndrome in SLE, acute reversible hypoxemia should be considered only after excluding thromboembolic disease.

■ Acute Lupus Pneumonitis

Acute lupus pneumonitis is a clinical syndrome with an underlying histology of DAD, bronchiolitis obliterans organizing pneumonia, NSIP, or a combination of these different forms of lung injury.[13] Acute lupus pneumonitis mimics an acute infectious pneumonia and may be the presenting manifestation of SLE in up to 50% of patients. In those with an established diagnosis, it also appears during a flare-up of the other systemic manifestations of SLE, particularly pleuritis, pericarditis, arthritis, and nephritis. Acute lupus pneumonitis is reportedly more common in the postpartum period. It frequently recurs and cases have been documented that have progressed to a more chronic interstitial lung disease (UIP). Fortunately, acute lupus pneumonitis is a relatively uncommon complication, occurring in less than 5% of patients.

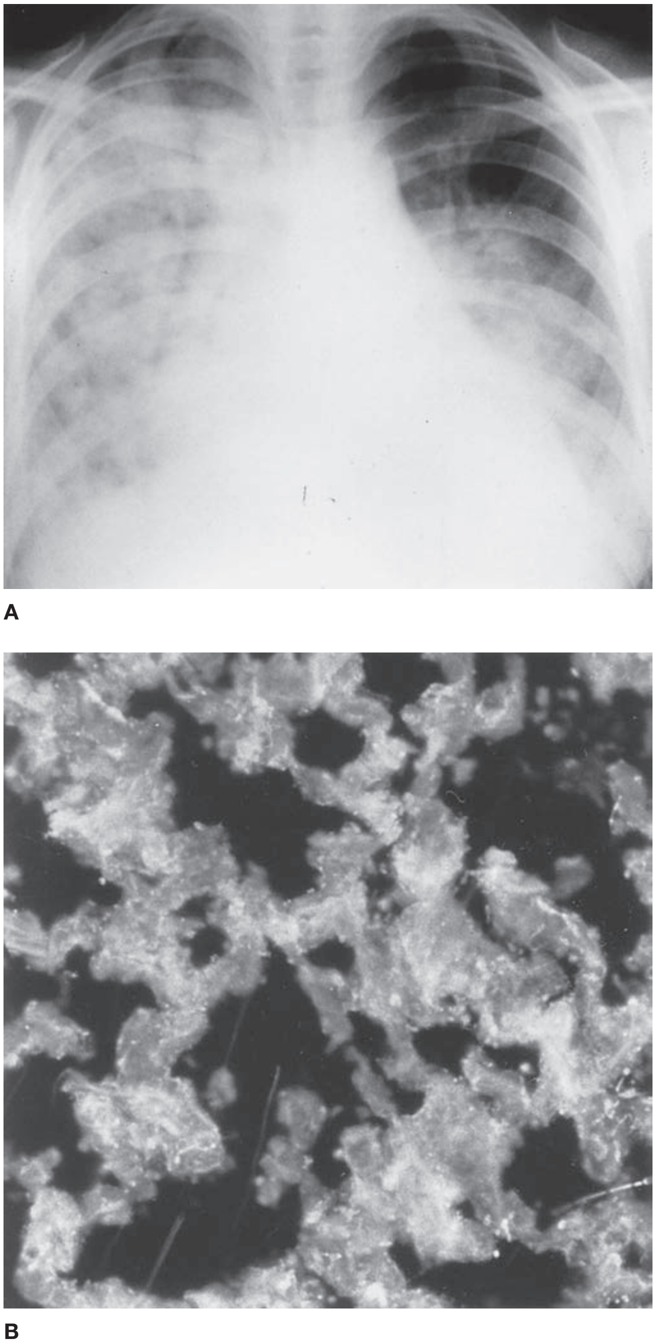

Figure 58-10 Acute lupus pneumonitis. **A.** The chest radiograph demonstrates diffuse alveolar filling with cardiomegaly (pericardial effusion vs. myocarditis). There is also a left pleural effusion. **B.** The immunofluorescent study demonstrates granular immune complex deposition in the alveolar interstitium.

Bilateral alveolar infiltrates, which can be patchy or densely consolidated and often accompanied by pleural effusions and cardiomegaly due to underlying pericardial effusion or myocarditis (Fig. 58-10A), are present on chest radiographs at presentation. White blood cell counts and sedimentation rates are elevated and serum complement is often low. Immunopathologic studies reveal the presence of complement as well as antibodies to IgG and DNA in some patients, supporting the concept of an immune complex pathogenesis (Fig. 58-10B). Because of the difficulty in distinguishing acute lupus pneumonitis from an infectious pneumonia, a bronchoalveolar lavage and sometimes an open (thoracoscopic) lung biopsy are indicated prior to instituting anti-inflammatory and immunosuppressive therapy. Acute respiratory failure in acute lupus pneumonitis often requires assisted mechanical ventilation. The mortality rate has been reported to be as high as 50%, with the causes of death in patients with acute lupus pneumonitis being respiratory failure, another complication of SLE (nephritis, cerebritis), or a superimposed infection.

■ Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage, although rare, may be a presenting manifestation of SLE. In several cases, recurrent diffuse alveolar hemorrhage was present for years prior to the diagnosis of SLE.[14] The majority of cases, in contrast to acute lupus pneumonitis, first appear in a well-documented case of SLE. Diffuse alveolar hemorrhage accounts for 1% to 4% of SLE-related hospitalizations.

Diffuse alveolar hemorrhage can also present with symptoms reminiscent of an infectious pneumonia or acute lupus pneumonitis, and the additional symptom of hemoptysis raises the possibility of this diagnosis. Hemoptysis is present in 30% to 50% of patients during their initial presentation, but up to 90% will have hemoptysis during their subsequent course. Routine laboratory work demonstrates a falling hematocrit, and in 60% to 90% of patients an active glomerulonephritis is present. A progressive serosanguineous bronchoalveolar lavage may be the first clue to this diagnosis. Diffuse alveolar infiltrates are present on chest radiography (Fig. 58-11), but in contrast to acute lupus pneumonitis, pleuritis and pericarditis are not prominent features. Pathologic changes that are reminiscent of both acute lupus pneumonitis (DAD and NSIP) and diffuse alveolar hemorrhage with or without pulmonary capillaritis are not unusual in a single biopsy specimen.[15] The mortality rate is approximately 50% and is independent of the underlying histopathology (bland hemorrhage vs. pulmonary capillaritis). Recurrent DAH is common and should be expected in the absence of therapeutic intervention.

There are no controlled clinical trials for the treatment of either acute lupus pneumonitis or diffuse alveolar hemorrhage. Once infection has been excluded, corticosteroids are the mainstay of therapy. Intravenous methylprednisolone, 1 to 2 g daily in divided doses for 3 to 4 days before tapering, should be considered. Concomitant oral or parenteral cyclophosphamide or azathioprine is commonly administered, given the associated incidence of lupus nephritis. Plasmapheresis, immunoglobulin therapy, and rituximab have been used successfully, consistent with the proposed immune complex pathogenesis.[16–19]

■ Lupus Pleuritis

Pleurisy and pleural effusion are the most common primary pulmonary complications of SLE, occurring in 50% to 80% of patients. Pleurisy and/or a pleural effusion may also be the presenting and sole manifestation of the disease. They are usually recurrent and may accompany more severe complications such as acute lupus pneumonitis or nephritis. Patients complain of pleuritic pain, fever, and dyspnea. The chest radiograph may be normal (dry pleurisy) or demonstrate small to moderate pleural effusions (massive effusions are rare), which are bilateral in 50% of patients. When unilateral, there is no predilection for either side.

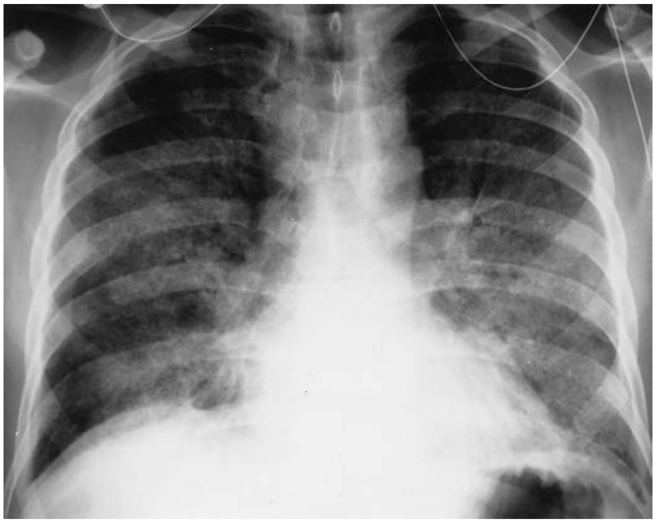

Figure 58-11 Diffuse alveolar hemorrhage in SLE. There are diffuse alveolar infiltrates without cardiomegaly or pleural effusions.

Effusions are serous or serosanguineous and exudative in nature. The white cell counts range from 5 to 10,000 cells/mm^3. Early on, neutrophils predominate, but with time mononuclear cells appear. These characteristics are nonspecific and are often seen with infectious parapneumonic effusions. In contrast to rheumatoid arthritis, the pleural fluid glucose concentration in lupus pleuritis is not reduced. Rheumatoid factor may be positive in lupus pleuritis. Pleural fluid complement levels are abnormally decreased in lupus, with both total complement activity and C3 and C4 reduced. A positive double-stranded pleural fluid DNA titer is nonspecific as opposed to the serum test since it has been found in pleural effusions due to malignancy and tuberculosis. The most helpful measurement is the pleural fluid antinuclear antibody titer. Levels greater than 1:160 are very suggestive of lupus pleuritis. Examination of the pleural tissue reveals infiltration with plasma cells and lymphocytes, and, with repeated episodes, pleural fibrosis supervenes. Occasionally, a vasculitis of the pleural vessels is detected, and immune complex deposition has been reported. Corticosteroid treatment is effective for relief of pleural pain, but time to resolution of the pleural effusion is quite variable and probably unaffected by this treatment. In the unusual case, recurrent lupus pleuritis may result in massive pleural fibrosis and lung entrapment, necessitating a pleural stripping procedure.

While pleural effusions and pleurisy are common in patients with SLE, a broad differential diagnosis should be considered. The increased incidence of infectious complications, thromboembolic disease, and pulmonary hypertension in SLE predisposes patients to parapneumonic effusions and empyema, congestive heart failure, and effusions secondary to thromboembolic disease.

■ Interstitial Lung Disease

Clinically significant interstitial lung disease is an uncommon pulmonary manifestation in SLE but UIP, lymphocytic interstitial pneumonitis, NSIP, and organizing pneumonia have all been reported. UIP is known to appear following acute lupus pneumonitis and in some cases has been documented to appear as an independent insidious disease. Using HRCT, 38% of patients with SLE patients with normal chest radiographs demonstrate pulmonary abnormalities consistent with some form of interstitial lung disease. In those who develop interstitial lung disease, a prior episode of acute lupus pneumonitis and an insidious onset of dyspnea are often noted. The prevalence of interstitial lung disease is increased in the subset of SLE patients with features suggestive of a mixed connective-tissue disease.

In patients who develop the insidious form of interstitial lung disease, the diagnosis of SLE is present for several years, and no other pattern of organ involvement predicts its appearance. These patients have progressive dyspnea and cough with interstitial infiltration on the chest radiograph. HRCT indicates combinations of ground-glass attenuation, inter- and intralobular septal thickening, and honeycomb change. Pulmonary function tests reveal a restrictive pattern with reduction in the diffusing capacity and hypoxemia accentuated by exercise. Response to therapy, either corticosteroids alone or in combination with cyclophosphamide or azathioprine, depends upon the underlying histology. Those cases with underlying NSIP or organizing pneumonia are more likely to respond to treatment than those who demonstrate excess collagen deposition and cystic honeycomb formation.

Pulmonary Vascular Disease

Pulmonary arterial hypertension, WHO Group 1, was previously thought to be an uncommon complication of SLE. It is now estimated to occur in 1% to 9% of patients.[20,21] This form of pulmonary hypertension is associated with Raynaud phenomenon, digital vasculitis, serositis, antibodies to ribonucleoprotein, rheumatoid factor, antiphospholipid antibodies, and most recently anti–endothelial cell antibodies. Patients complain of dyspnea and fatigue but have normal chest radiographs. In advanced cases, pulmonary arterial enlargement appears. Spirometry and lung volumes are normal, but there is often an isolated reduction of the diffusing capacity for carbon monoxide as well as gas exchange abnormalities. Ventilation–perfusion lung scanning and, occasionally, pulmonary arteriography are indicated, particularly in those patients with the antiphospholipid syndrome who have a potential for recurrent small pulmonary emboli. Therapeutic options include vasodilator therapy, anticoagulation, immunosuppression with cyclophosphamide, and transplantation.

Vasculitis in SLE is more likely to be discovered in lung biopsy specimens, demonstrating either diffuse alveolar hemorrhage or acute lupus pneumonitis as opposed to being an isolated finding. Autopsy series indicate small-vessel vasculitis in 20% of cases.

Airway Disease

Five percent of SLE patients are reported also to have obstructive physiology. Obliterative bronchiolitis has been documented in SLE but is rare in contrast to rheumatoid arthritis. Organizing pneumonia, with inflammatory polyps protruding into bronchiolar lumens, is one of the interstitial patterns that occurs in acute lupus pneumonitis and in chronic interstitial lung disease in SLE, but this entity causes restriction rather than obstructive lung disease. Bronchiectasis may occur in up 20% of patients but is often asymptomatic. Large airway involvement including tracheal and subglottic stenosis, vocal fold paralysis, epiglottitis, and necrotizing tracheitis have all been reported, but are rare.

Respiratory Muscle Dysfunction

It is estimated that weakness of the diaphragm and other respiratory muscles is found in 25% of patients with SLE. This accounts for the previously unexplained findings of dyspnea without evidence of interstitial or pulmonary vascular disease. These patients have subsegmental atelectasis, an elevated diaphragm on chest radiograph (Fig. 58-12), and restrictive physiology. This has been referred to as *unexplained dyspnea and shrinking lung syndrome.* Although there is a reduction in static lung volumes, the diffusing capacity, when corrected for alveolar volume, remains normal, thereby distinguishing respiratory muscle dysfunction from interstitial lung disease. The likely explanation for this is a reduction in the transdiaphragmatic pressure generated during maximal inspiration, which in turn reduces static lung compliance, producing the linear atelectasis seen on the chest radiograph. Moreover, in the patients with respiratory muscle weakness, no evidence for a generalized neuromuscular disease can be found. The pathogenesis of respiratory muscle dysfunction remains unexplained, although phrenic nerve conduction abnormalities have been excluded.[22] Abnormal diaphragmatic activation, due in part to voluntary inhibition due to pleuritic pain, may contribute to diaphragmatic dysfunction in this disorder. Clinical variables associated with the development of shrinking lung syndrome include pleuritis, double-stranded DNA antibody and RNP antibody seropositivity, serositis, and a prolonged course of SLE.[7] Corticosteroids are not a frequently effective treatment modality. Rituximab has been used successfully in the treatment of shrinking lung syndrome, albeit anecdotally in nature.[23] Progression is uncommon and most patients stabilize. Positive-pressure ventilation, particularly at night, may improve these patients' daytime symptoms, although there is limited evidence available. Rituximab has been used successfully in patients with respiratory muscle dysfunction with significant physiologic improvement.[23]

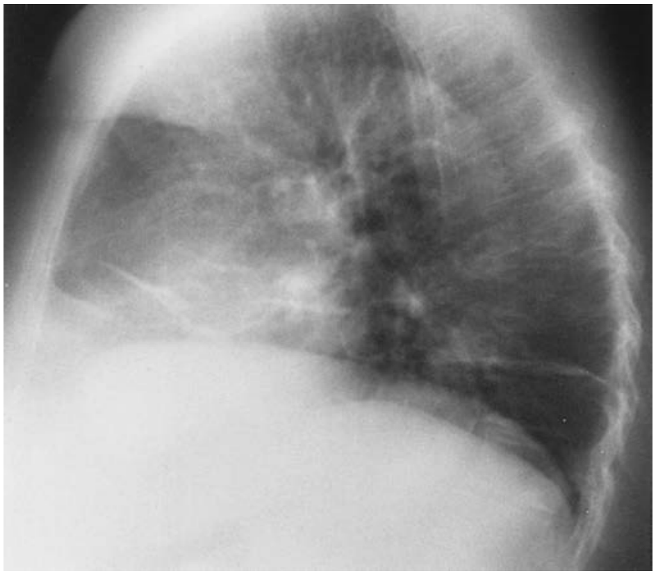

Figure 58-12 Diaphragmatic dysfunction in SLE. There is diaphragmatic elevation resulting in plate-like atelectasis.

RHEUMATOID ARTHRITIS: CLINICAL FEATURES

Rheumatoid arthritis classically affects the articular surfaces, but pleuropulmonary complications are responsible for significantly increased morbidity and mortality.[24] Most often cited is a 50% incidence for these complications, but it is likely that this underestimates their frequency.[25] Rheumatoid arthritis–associated interstitial lung disease abnormalities may be present in more than 60% of patients with RA and are clinically asymptomatic during the initial assessment.[26] In those that manifest symptoms—dry cough, chest pain, dyspnea, and others—the presence of RA-ILD, which approximates 10%, is associated with increased mortality.[27–29] Pleuropulmonary complications, including interstitial lung disease, are more apt to occur in patients with more severe chronic articular disease, with high titers of rheumatoid factor, and in patients who have subcutaneous nodules, as well as other systemic complications such as cutaneous vasculitis, myocarditis, pericarditis, ocular inflammation, and Felty syndrome.

An association between smoking and an increased risk for the development of pleuropulmonary disease, radiographic progression, and nodule formation in rheumatoid factor–seropositive patients has been reported. Several series suggest that in those patients with anti–citrullinated protein (CCP) antibodies there is an increase in parenchymal lung abnormalities, independent of current or prior tobacco exposure, supportive of the hypotheses that anti-CCPs are associated with ILD in RA and that high titers may correlate with the development of ILD.[30–32] Specific genetic factors, such as the MUC5B promoter variant rs35705950, also serve as increased risk factors for the development of RA-ILD.[33] Furthermore, elevated serum KL-6 levels have been identified as another possible risk factor, as studies performed on small groups of RA patients found elevated KL-6 levels in more than 88% of patients with active RA-ILD.[34] Additional biomarker signatures are being investigated and validated to identify patients with RA who are at risk of developing ILD and identify them earlier in their course.[35]

Pleuropulmonary disease may occur in seronegative patients, and both cytolytic and biologic therapies, commonly employed for treatment, can induce an interstitial lung disease that is often difficult to distinguish from the primary forms complicating rheumatoid arthritis.[36] Moreover, interstitial lung disease, pleuritis, and occasionally obliterative bronchiolitis may be the first and only manifestation of the rheumatoid state in up to 20% of patients, preceding the articular manifestations by months to years.

Several therapeutic agents have been suggested in literature, but the optimal treatment has yet to be recorded. These agents include immunosuppressive drugs, disease-modifying antirheumatic drugs (DMARDs), and biologic drugs. Corticosteroids are often the first line of therapy with secondary treatments soon to follow. Often cited secondary agents are methotrexate, rituximab, and TNF-α among others. Treatment is highly controversial and personalized due to the varied clinical, radiologic, and histologic spectra of RA-ILD and the risk of worsening symptoms. It is thought that early diagnosis and treatment of the disease greatly contributes to reduced morbidity and mortality.

■ Pleurisy and Pleural Effusion

In a postmortem series, pleural disease was found in 40% of patients with rheumatoid arthritis. The incidence of clinically apparent pleural disease is closer to 5%, and most patients experience mild symptoms. In approximately 20% of the patients who develop pleural complications, they do so prior to the onset of articular disease. In patients with rheumatoid arthritis, pleural complications are more common in men and occur most frequently during episodes of active articular disease and in patients with subcutaneous rheumatoid nodules.

Pleural disease is often first discovered on routine chest radiograph, and both pleural fibrosis and effusions have been reported to occur in otherwise asymptomatic patients. In one series using multidetector CT imaging, pleural thickening was noted in 49% of patients and did not correlate to the presence of symptoms.[37] Pleural effusions can be unilateral or bilateral and coexist with interstitial lung disease or necrobiotic nodules. Symptomatic patients present with pleuritic pain, dyspnea, and occasionally fever. The effusion is an exudate by protein and lactic dehydrogenase criteria, and, if chronic, cholesterol concentrations are increased. Other characteristics include a low pleural fluid pH (<7.2), thought to be due to enhanced glucose metabolism within the inflamed pleural space with resultant lactate and carbon dioxide production. The leukocyte counts can be as high as 15,000 cells/mm^3 and consist of a mixture of neutrophils and mononuclear leukocytes. As in SLE, the total and individual complement components are low, and the rheumatoid factor level is increased. The presence of rheumatoid factor in pleural fluid has also been reported with tuberculosis, malignancy, and other infectious diseases. A low pleural fluid glucose concentration, thought to be due to a defect in glucose transport, is characteristic of rheumatoid effusions. Up to 40% of patients have pleural fluid glucose levels less than 10 mg/dL, and 75% have levels under 50 mg/dL. It has been stated that cytologic examination of the pleural fluid, which demonstrates a background of necrotic debris, spindle-shaped macrophages, and multinucleated histiocytes, is characteristic of a rheumatoid effusion. Necrobiotic nodules are thought to be involved in the pathogenesis of the pleural effusions, but transthoracic pleural biopsy only occasionally will demonstrate this finding.

Treatment is not indicated for asymptomatic cases; however, corticosteroids, when used for active articular disease, are also effective in hastening the resolution of the pleural effusion. Rarely is any other form of intervention such as intrapleural corticosteroids necessary for these patients. In the unusual case, pleural fibrosis with resultant lung entrapment occurs, requiring surgical intervention. Spontaneous pneumothorax due to rupture of a necrobiotic nodule, another uncommon complication, necessitates tube thoracostomy, and with persistence of the bronchopleural fistula, surgical intervention is indicated.

■ Pulmonary Vascular Disease

In general, pulmonary vascular disease is the least common pleuropulmonary complication in rheumatoid arthritis. When it does occur, Raynaud phenomenon is commonly present. The chest radiograph reveals normal lung fields and enlarged pulmonary arteries, and there is an isolated reduction of the diffusing capacity for carbon monoxide as well as hypoxemia.

Small-vessel vasculitis in rheumatoid arthritis occurs in the setting of diffuse alveolar hemorrhage due to pulmonary capillaritis and is a very rare event in rheumatoid arthritis. Several cases have been well documented; in one, antineutrophilic cytoplasmic antibody to myeloperoxidase (p-ANCA) was present in the serum. Treatment with intravenous methylprednisolone, followed by oral corticosteroid preparations in addition to cyclophosphamide, is indicated for this complication. As noted with other systemic vasculitides, rituximab induces remission and reduces prednisone exposure in a significant proportion of patients with systemic rheumatoid vasculitis.[38]

■ Necrobiotic (Rheumatoid) Nodule

Radiographically visible parenchymal rheumatoid nodules are infrequently seen in a rheumatoid population (1%). If present, necrobiotic nodules are more common in men, particularly those who smoke, with active articular disease and high rheumatoid factors, and in those who have subcutaneous nodules. The nodules are primarily a radiographic finding, subpleural in distribution, and asymptomatic in most. Cavitation and rupture may occur rarely and are associated with pneumothorax, pleural effusions, and hemoptysis. Radiographically, the nodules can be single or multiple with upper- and midzone predilection, and approximately 50% will undergo cavitation due to the large amounts of proteolytic enzymes in these lesions. The size is variable, and nodules up to 7 cm have been reported. Spontaneous resolution and recurrence are to be expected. Continuous growth should prompt a more aggressive diagnostic approach. In most cases, no treatment is required. The major problem is differentiating the necrobiotic nodule from either malignant or infectious granulomatous disease, particularly given the increased risk of lung cancer in patients with RA.[39]

Caplan syndrome refers to a radiographic abnormality that developed in Welsh coal miners with rheumatoid arthritis and a pneumoconiosis.[40] It consists of the sudden appearance of discrete nodules primarily in the upper lobes that are histologically identical to the necrobiotic nodule (Fig. 58-13). The incidence of necrobiotic nodules is higher in rheumatoid patients with underlying pneumoconiosis, including coal workers' pneumoconiosis, silicosis, and asbestosis, than it is in a general rheumatoid population.

■ Airway Disease

Upper airway involvement by the rheumatoid process most commonly involves the cricoarytenoid joint, causing difficulty with inspiration and occasionally resulting in stridor. A sore throat, hoarseness, and globus sensation are other common complaints. The prevalence of this complication, although asymptomatic in most cases, approaches 50% when CT screening is employed. Clinically significant disease can be detected by performing flow–volume loops, which indicate a variable extrathoracic obstruction of the inspiratory loop. Cricoarytenoid arthritis may further complicate endotracheal intubation and should be considered in all patients with rheumatoid arthritis requiring general anesthesia.

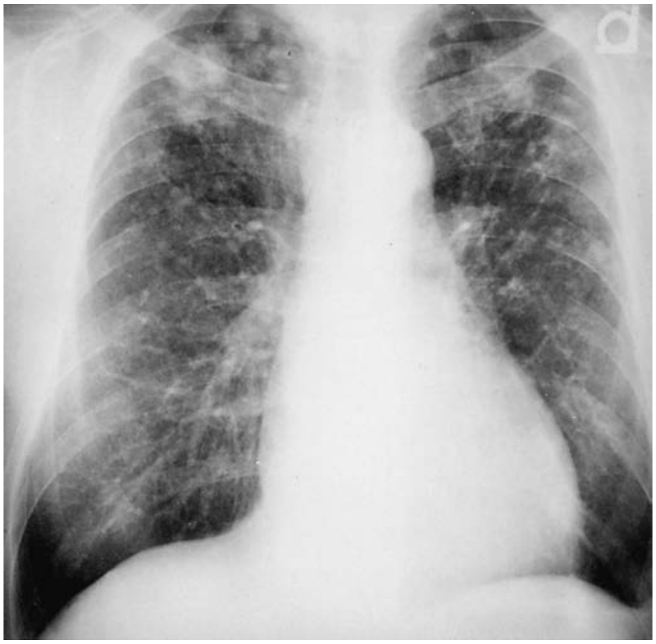

Figure 58-13 Caplan syndrome in a patient with rheumatoid arthritis and silicosis (hard-rock miner). There are multiple small nodules in the middle and upper lung representing the silicosis. In addition, multiple upper-zone rheumatoid nodules are present.

Bronchiolitis obliterans or obliterative bronchiolitis is a well-recognized cause of progressive and often severe obstructive lung disease in patients with rheumatoid arthritis.[41] The majority of patients develop bronchiolitis subsequent to the diagnosis of RA. Of note, bronchiolitis obliterans may be the initial manifestation of RA in a small group of patients.[42] This complication was first thought to be a consequence of either penicillamine or gold therapy, but many cases have appeared in the absence of either treatment. The onset of obliterative bronchiolitis is insidious, with patients complaining of progressive dyspnea and cough while having a normal or hyperinflated chest radiograph (Fig. 58-14A). It was thought that this complication was limited to women, but this is not the case. Physical examination reveals a generalized reduction of breath sounds and occasionally an inspiratory squeak. Physiologic testing reveals varying degrees of airflow limitation and hyperinflation, and the diffusing capacity may be normal or reduced. HRCT demonstrates adjacent areas of decreased and increased attenuation (geographic pattern), suggesting air trapping, which may be further identified by expiratory imaging (Fig. 58-14B). The response to therapy is generally poor. Some patients have responded to treatment with a combination of corticosteroids and cyclophosphamide, but most cases progress to hypercapnic respiratory failure.

Another form of bronchiolitis seen in RA is a respiratory or follicular bronchiolitis, consisting of a dense infiltration of lymphocytes and plasma cells surrounding the terminal and respiratory bronchioles. Cough and dyspnea are common symptoms. Chest radiographs may be normal or demonstrate a fine nodular pattern more predominant in the middle and lower lung zones. HRCT reveals a pattern of follicular bronchiolitis in up to 33% of patients with RA, demonstrating centrilobular nodules and bronchiectasis (Fig. 58-15).[37] There is usually no physiologic evidence for airflow limitation or reduced lung volumes, but rather gas exchange abnormalities dominate the physiologic picture. Treatment with corticosteroids yields variable results.

Diffuse panbronchiolitis has been reported in Japanese patients with RA. In both diffuse panbronchiolitis and rheumatoid arthritis, an association with HLADR4 and B54 haplotypes has been reported, suggesting a common genetic predisposition.[43,44]

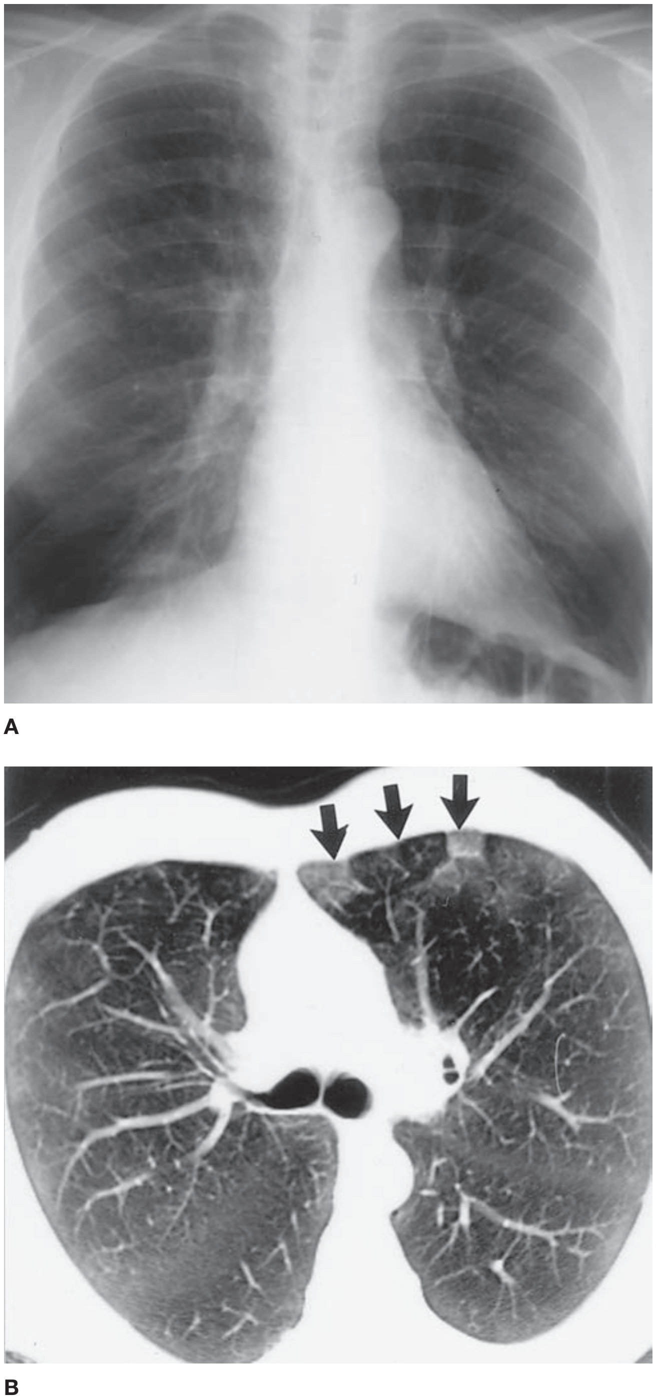

Figure 58-14 Obliterative bronchiolitis in a patient with rheumatoid arthritis. **A.** The chest radiograph is normal except for hyperinflation. **B.** HRCT demonstrating areas of increased and decreased attenuation *(arrows)*.

■ Interstitial Lung Disease

Interstitial lung disease is a relatively common complication in patients with rheumatoid arthritis. In contrast to most connective-tissue diseases, interstitial lung disease is more common in males than females (3:1), in individuals who have late-onset disease and high-titer rheumatoid factors, and in those who smoke. More recent series suggest that the presence and titer of anti–citrullinated protein antibodies are associated with ILD on HRCT imaging of

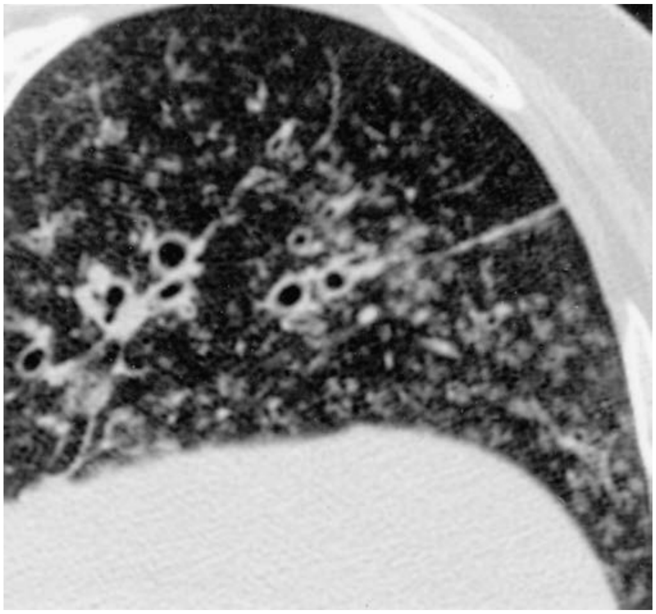

Figure 58-15 Follicular bronchiolitis in rheumatoid arthritis. HRCT demonstrating multiple centrilobular nodules.

the chest in patients with RA.[45] It is not unusual for interstitial lung disease to precede the articular manifestations for a period of months to years. The incidence of this complication in a rheumatoid population is difficult to determine, being reported in 5% to 40% of patients depending upon the methods of detection. The use of bronchoalveolar lavage indicating alveolar inflammation and HRCT scans indicating various interstitial changes, often in the face of a negative chest radiograph, are difficult to interpret. This is because follow-up studies determining whether these patients developed clinically apparent interstitial lung disease are lacking. Furthermore, some parenchymal changes described on CT such as bronchiectasis have very little, if any, clinical significance. It is likely that clinically important interstitial lung disease occurs in 5% to 10% of patients with rheumatoid arthritis, the most common forms being UIP followed by NSIP.[45,46] These patients are dyspneic and complain of cough. Physical examination reveals bibasilar crackles, clubbing of the digits, and evidence of cor pulmonale when pulmonary hypertension appears secondary to hypoxic vasoconstriction. The chest radiograph and CT scan demonstrate varying degrees of interstitial infiltrates with predilection for the lung bases and lung periphery (Fig. 58-16A). Other features include ground-glass attenuation on CT with mixed alveolar–interstitial infiltrates on chest radiograph indicating a component of NSIP. Both imaging studies in advanced disease reveal the presence of honeycomb lung (Fig. 58-16B).

Several other interstitial reactions, which produce subacute or chronic symptoms, complicate RA. The first is organizing pneumonia, which can present with symptoms identical to UIP and preempt the onset of the articular disease as well. The chest radiograph (Fig. 58-17) and CT scan differ from that seen in UIP because the infiltrates are primarily alveolar and localized, patchy, or diffuse. The second interstitial reaction is lymphocytic interstitial pneumonia, which occurs when RA is complicated by Sjögren syndrome. In addition to dyspnea and cough, these patients complain of dry mouth and eyes (xerophthalmia and xerostomia). The chest radiograph indicates patchy alveolar infiltrates primarily seen at the lung bases. In contrast to patients with primary Sjögren syndrome in which large cystic structures may develop within the lung, parenchymal cysts are uncommon in patients with RA-ILD. Eosinophilic pneumonia has been reported as a pleuroparenchymal complication of RA and may be the primary presentation of the disease. Acute interstitial pneumonitis is a rare, acute form of interstitial lung disease in RA. While it may occur as a result of an immunologic injury to the lung, medication-related pulmonary toxicity and opportunistic infections should be considered. Finally, fibrobullous disease, similar to that seen in ankylosing spondylitis, has been reported in RA and may precede the articular manifestations of the disease.

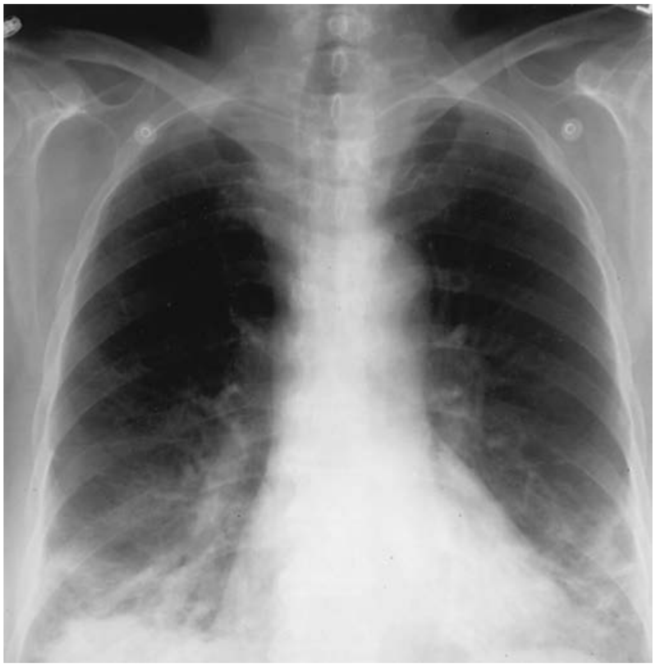

Figure 58-17 Organizing pneumonia in rheumatoid arthritis. Chest radiograph demonstrating lower-zone mixed alveolar-interstitial infiltrates.

It is important to establish the underlying histology since response to therapy and prognosis differs. Unless the imaging studies indicate end-stage honeycomb lung, which can also result from unresponsive or recurrent organizing pneumonia, lymphocytic interstitial pneumonia, or UIP, further evaluation is indicated. Bronchoalveolar lavage will not necessarily help differentiate between these three histologic pictures, but the finding of increased lymphocytic percentages as opposed to neutrophils and eosinophils indicates the potential for therapeutic responsiveness. Alveolar infiltrates and increased lymphocyte percentages are seen in lymphocytic interstitial pneumonitis. Organizing pneumonia is associated with increases in neutrophil, eosinophil, and lymphocyte percentages as well as radiographic alveolar infiltrates. The finding of increased neutrophil and eosinophil percentages in suspected underlying UIP is an indicator of poor prognosis. Therefore, patients with lymphocytic interstitial pneumonitis and organizing pneumonia are more treatment responsive when compared to those with UIP. If imaging studies and bronchoalveolar lavage cellular analysis are not definitive, thoracoscopic open lung biopsy should be considered. Treatment consists of a corticosteroid preparation and often the addition of cytotoxic drugs in the nonresponsive cases. As opposed to the idiopathic variety of organizing pneumonia, in which 66% of cases have favorable responses to corticosteroid medications, those associated with collagen vascular diseases are less responsive to treatment, often recur with tapering of the treatment regimen, and can progress to honeycomb lung. While the histopathology may be similar between RA and idiopathic pulmonary fibrosis, improved survival exists for those with rheumatoid arthritis–associated UIP but the long-term prognosis remains poor.[27,28,30,47]

Gold-induced pneumonitis must be differentiated from the primary forms of interstitial lung disease in patients with RA, particularly since the underlying histology can be similar, indicating varying degrees of NSIP and organizing pneumonia.[48] Dyspnea and cough usually begin 4 to 6 weeks following initiation of therapy, and peripheral eosinophilia occurs in a minority of cases. Occasionally, the chest radiograph will demonstrate upper- as opposed to lower-zone mixed alveolar interstitial infiltration. Bronchoalveolar lavage indicates a predominance of lymphocytes, and differentiation from rheumatoid interstitial lung disease can only be made after withdrawal of the drug results in remission. In severe cases with marked gas exchange abnormalities, corticosteroid therapy will occasion prompt reversal.

Methotrexate given in relatively low weekly doses (10–20 mg) is associated with the development of an interstitial disease in rheumatoid patients. No correlation with age, sex, duration of disease, or weekly or cumulative dose could be found. Conflicting data suggest that rheumatoid patients with underlying primary rheumatoid lung disease are predisposed to develop methotrexate pneumonitis. In rheumatoid patients treated with methotrexate, the incidence of methotrexate pneumonitis is 1% to 11%. The clinical onset is relatively acute with cough, fever, dyspnea, and new mixed alveolar and interstitial pulmonary infiltrates on chest radiograph. Increased white blood cell counts with mild eosinophilia, elevated sedimentation rates, and increased serum lactic dehydrogenase are nonspecific findings. Bronchoalveolar lavage indicates lymphocytosis and should be performed to rule out an infectious etiology. Lung tissue reveals an NSIP, organizing pneumonia, and granuloma formation reminiscent of a hypersensitivity pneumonitis. In patients who develop this clinical syndrome while on methotrexate, the drug should be discontinued since progression to end-stage fibrosis may occur. With life-threatening respiratory failure, corticosteroids given intravenously are an effective therapy.

The advent of TNF-α antagonists has revolutionized therapy for patients with RA. Their efficacy in the treatment of pleuroparenchymal complications remains unknown, with conflicting data having been reported. Of concern in those patients being treated with these agents should be the increased risk of infections, particularly both typical and atypical mycobacteria and fungi, as well as common bacterial pathogens. Several series suggest a temporal association between the use of TNF-α antagonists and the development of ILD. It remains unclear if the association is temporal or causative.[36,49–52] The compendium of therapies that have been evaluated for the treatment of RA has not been thoroughly evaluated to assess efficacy in the treatment of ILD. In those with a progressive fibrosing ILD (including RA-ILD) in the preceding 24 months, particularly with an underlying UIP radiographic pattern, nintedanib has been demonstrated to reduce the annual rate of decline of FVC compared to placebo.[53]

SYSTEMIC SCLEROSIS: CLINICAL FEATURES

Systemic sclerosis (scleroderma) is an inflammatory-fibrotic disease that results in deposition of excessive extracellular matrix in the skin and several visceral organs including the lungs, heart, kidneys, and gastrointestinal tract. Two subtypes of systemic sclerosis exist: diffuse cutaneous and limited cutaneous forms. In diffuse systemic sclerosis, extensive skin involvement of the extremities, face, and torso exists with accompanying marked visceral involvement that is progressive in nature. The limited cutaneous form, previously termed CREST variant (*c*alcinosis, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasias), has a more protracted course in most patients and usually affects an older subset of patients. Pulmonary disease contributes significantly to both the morbidity and mortality of patients. The pathogenesis, although not well understood, involves a complex interaction among immune cells, endothelial cells, and fibroblasts. In addition to the excessive extracellular matrix, which in the lung results in interstitial fibrosis, endothelial cell damage with intimal thickening of pulmonary and systemic arteries occurs, leading to luminal obliteration. This may result in a form of pulmonary arterial hypertension (WHO Group 1).

The lung is involved in the great majority of cases of systemic sclerosis, with postmortem series indicating a 70% to 100% incidence.[54] Most patients with systemic sclerosis develop dyspnea during the course of their illness due to either interstitial lung disease or pulmonary hypertension. Both bronchoalveolar lavage and HRCT

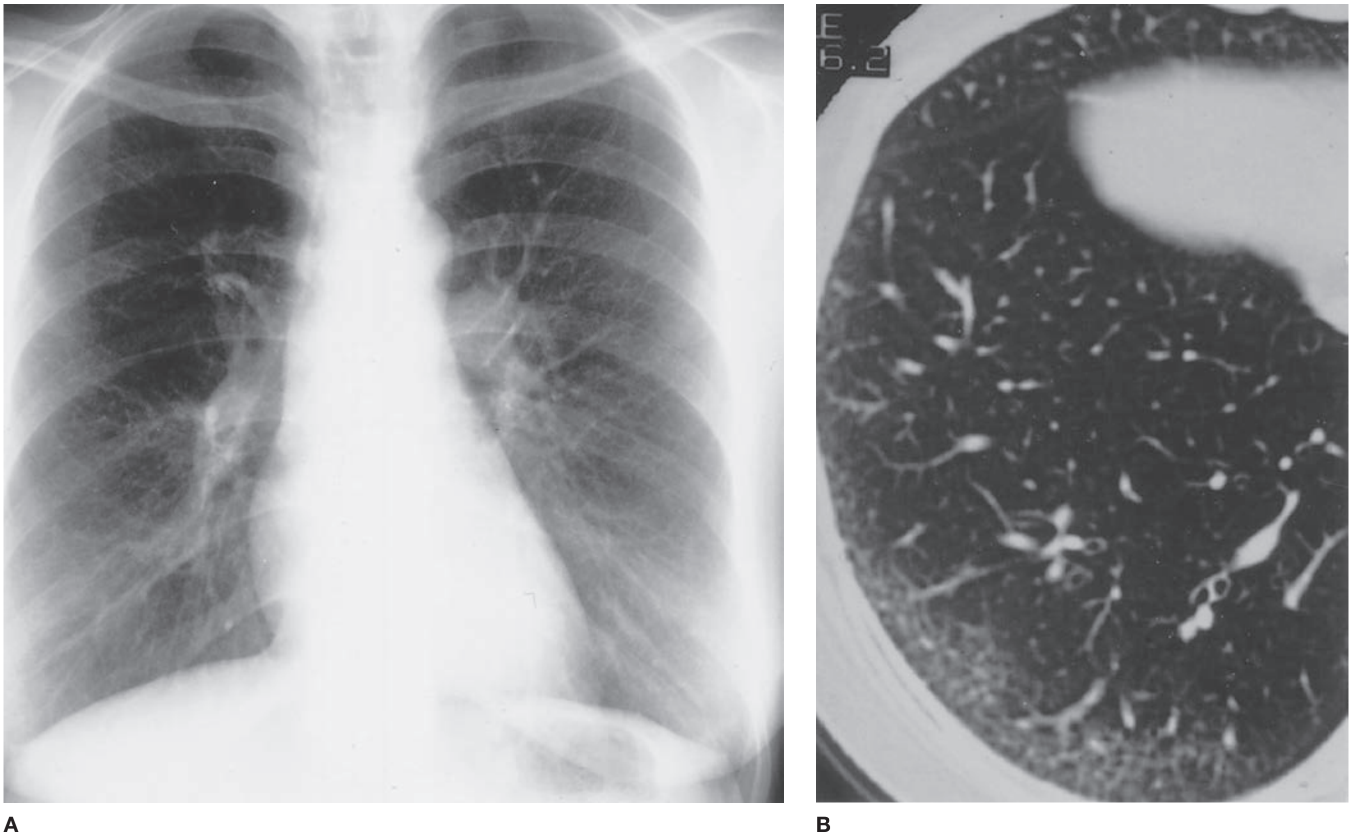

Figure 58-18 **A.** Normal chest radiograph in a dyspneic patient with scleroderma. **B.** HRCT of the same patient demonstrating reticular interstitial infiltrates.

scans, in the face of normal chest radiographs, have indicated interstitial lung disease in both symptomatic and asymptomatic patients (Fig. 58-18). Although unusual, interstitial lung disease and pulmonary hypertension have preceded the dermatologic manifestations, defined as systemic sclerosis sine scleroderma.[55] Despite the lack of skin involvement, the course in systemic sclerosis sine scleroderma does not significantly differ from the more common forms, with the exception of a greater tendency toward the development of pulmonary hypertension.

■ Pleural Disease

Although pleural fibrosis and adhesions are reported to be present in 40% of patients with scleroderma in postmortem studies, clinically apparent pleural thickening or pleural effusions on chest radiographs are considerably less frequent. The exception to this is pleural effusions secondary to congestive heart failure due to a systemic sclerosis–associated cardiomyopathy or cor pulmonale associated with pulmonary arterial hypertension.

■ Interstitial Lung Disease

Interstitial lung disease is the most common pulmonary complication of scleroderma, occurring in 30% to 100% of cases. An HRCT study indicated a greater than 90% incidence of this abnormality with up to two-thirds of patients having normal chest radiographs. As many as 60% of patients who undergo BAL will demonstrate an abnormal inflammatory cell distribution. Chest radiographic and physiologic screenings indicate somewhat lower prevalence. The significance of the BAL and CT findings remains unclear, since no longitudinal follow-up is available. Following the histologic reclassification of idiopathic interstitial pneumonias, the most common underlying histology in systemic sclerosis is NSIP with honeycomb lung. UIP, unclassifiable fibrosing interstitial lung disease, and rarely, organizing pneumonia and granulomatous lung disease resembling sarcoidosis also have been reported.[56] It was previously thought that interstitial lung disease in scleroderma was primarily a fibrotic disorder. However, recent information derived from HRCT demonstrating ground-glass attenuation, which indicates more cellular disease, BAL revealing increased inflammatory cell populations, and biopsy material demonstrating cellular infiltration of the interstitium indicates the presence of a cellular inflammatory response.[57] This predates the development of fibrosis, consistent with the cellular subtype of NSIP. It is likely that the inflammatory phase in most cases is clinically silent.

Interstitial lung disease is more likely to occur in diffuse systemic sclerosis, although it may also complicate limited systemic sclerosis, formerly referred to as the CREST syndrome. Dyspnea on exertion progressing to dyspnea at rest and cough are the predominant symptoms. Bibasilar crackles are heard, but clubbing is unusual due to the capillary destruction in the nail beds. Physical findings of cor pulmonale eventually appear. Bibasilar interstitial infiltrates followed by more diffuse changes, loss of lung volume, honeycomb cysts, and pulmonary hypertension are the typical radiographic features. Scleroderma was the first interstitial lung disease in which scar carcinoma (adenocarcinoma or alveolar cell carcinoma) was reported. Several reports suggest an increased incidence of lung neoplasms in patients with scleroderma.[58,59] Physiologic testing eventually reveals restrictive lung disease, preserved flow rates, and reduced diffusing capacity. Early on, the aforementioned measurements may be normal, and hypoxemia and a widened alveolar–arterial oxygen gradient at rest and heightened by exercise may be the only physiologic abnormality. A disproportionally greater reduction[60] of the diffusing capacity, when compared with lung volumes, most likely indicates the presence of pulmonary arterial hypertension, particularly in the limited cutaneous form of systemic sclerosis.

Other forms of interstitial lung disease seen in scleroderma include lymphocytic interstitial pneumonitis in those cases associated with Sjögren syndrome; rare cases of diffuse alveolar hemorrhage, and DAD in association with exacerbations of fibrotic lung disease in scleroderma have been reported.

Immunosuppression has been the mainstay of treatment, with corticosteroids and cyclophosphamide previously being the agents of choice. The NHLBI-sponsored Scleroderma Lung Study I confirmed prior retrospective studies suggesting improved lung function in those patients treated with cyclophosphamide. Although the improvement in lung function is of questionable clinical significance, a therapeutic effect is expected in those with ground-glass attenuation on HRCT imaging, a lymphocytic- or eosinophilic-predominant BAL, and a cellular interstitial pneumonia on lung biopsy.[61,62] Unfortunately, the durability of response to cyclophosphamide was limited, as the majority of physiologic benefit waned after 12 months of discontinuation of treatment.[63] In Scleroderma Lung Study II, treatment with mycophenolate mofetil for 24 months was associated with significant improvement in FVC percent predicted, quantitative lung fibrosis score, and patient-related outcomes (PROs). While there were no significant differences between cyclophosphamide and mycophenolate mofetil in terms of efficacy in SLS II, the tolerability and safety profile of mycophenolate mofetil is superior.[64] In a small, randomized, controlled trial, rituximab was reported to benefit patients with progressive disease in scleroderma with physiologic and radiographic improvement.[65] In an international, multicenter, randomized, placebo-controlled trial, nintedanib, which was originally approved for the treatment of idiopathic pulmonary fibrosis, reduced the annual rate of decline in FVC. No additional benefit for the nonpulmonary manifestations of systemic sclerosis was noted.[66] In a randomized, placebo-controlled trial of patients with systemic sclerosis with progressive skin disease and ILD, tocilizumab, a monoclonal antibody against the interleukin 6 (IL-6) receptor, preserved FVC at 48 weeks.[67]

Pulmonary Vascular Disease

Pulmonary arterial hypertension (WHO Group 1) occurs in approximately 10% of cases of systemic sclerosis and is primarily seen in the limited cutaneous form (CREST syndrome). In this form of systemic sclerosis, pulmonary arterial hypertension may coexist with interstitial lung disease. Patients present with a gradual onset of dyspnea and increasing fatigue. Physical examination and chest radiograph may initially be normal, and, with disease progression, physical and radiographic signs of pulmonary hypertension appear. Lung volumes and airflow parameters are maintained, unless there is concomitant interstitial lung disease. Typically, there is an isolated reduction in the diffusing capacity as well as progressive hypoxemia. Prior to the use of vasodilator therapy, the mean survival following a diagnosis of pulmonary arterial hypertension was approximately 2 years. Treatment with continuous intravenous prostacyclin, phosphodiesterase type 5 inhibitors, and endothelin antagonists have improved quality of life and exercise performance. Improved survival has been suggested with the use of these agents, specifically in those patients with isolated pulmonary arterial hypertension, in contrast to those with ILD-associated pulmonary hypertension.[68]

Aspiration Pneumonia

There is a high incidence of esophageal dilatation and decreased peristalsis (dysmotility) in patients with scleroderma, particularly in the limited variety (Fig. 58-19). This leads to dysphagia, heartburn, gastroesophageal reflux, and possibly aspiration with subsequent pneumonia.[69] It has long been held that reflux and aspiration contribute to the development of interstitial lung disease, albeit with a paucity of direct evidence.[70] In scleroderma, several different abnormalities contribute to the risk of reflux and aspiration: altered peristalsis, reduced lower esophageal pressure, presence of a hiatal hernia, gastroparesis, and autonomic nerve dysfunction.[71] Aggressive treatment to reduce the risk of reflux and aspiration is recommended despite inconclusive evidence to suggest an association. Behavioral modification and pharmacologic acid suppression are the initial interventions. In refractory situations, fundoplication may be considered in the appropriate patient, particularly in those with advanced lung fibrosis awaiting transplantation in an attempt to decrease the incidence of posttransplantation bronchiolitis obliterans and chronic rejection.[72–74]

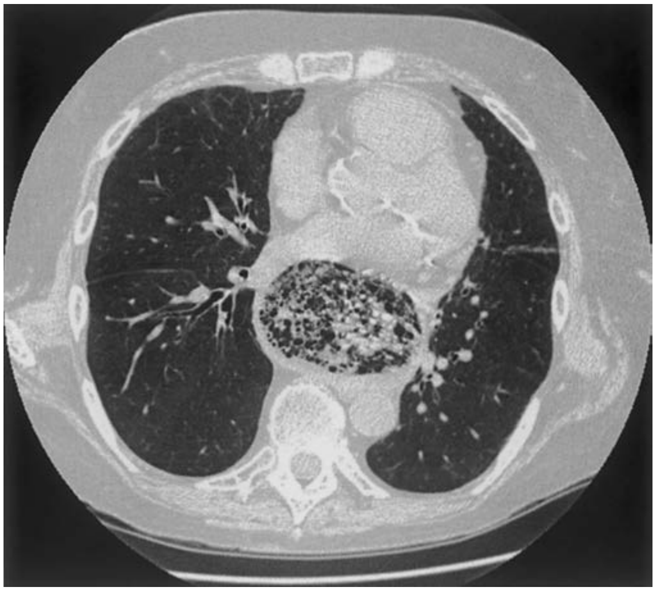

Figure 58-19 Mild peripheral, linear, ground-glass opacities in both lungs with marked thickening of the esophageal wall and severe dilatation of esophageal lumen with extensive debris filling the lumen in a patient with limited systemic sclerosis.

POLYMYOSITIS-DERMATOMYOSITIS: CLINICAL FEATURES

Polymyositis is a systemic autoimmune disorder characterized by an inflammatory myopathy. Dermatomyositis differs from polymyositis in that prominent skin involvement, characterized by a heliotropic rash and/or erythematosus scaling over the proximal interphalangeal joints, termed *Gottron papules* or *rash*, occurs with less severe myositis. In polymyositis–dermatomyositis, pulmonary complications are common and important causes of morbidity and mortality. As seen in other connective-tissue diseases, these complications often predate or overshadow the muscle or skin manifestations. Pulmonary involvement has been reported in up to 40% of cases.[75] In contrast to the other collagen vascular diseases, in polymyositis–dermatomyositis primary involvement of the airways and pleura do not routinely occur. Pulmonary arterial hypertension (WHO Group 1) has been reported on several occasions, most often in cases in which a crossover with scleroderma was suspected.

Aspiration Pneumonia

Aspiration pneumonia is a common pulmonary complication, occurring in 10% to 20% of patients with polymyositis–dermatomyositis; almost half of the patients complain of dysphagia as well. This complication results from an inflammatory myositis affecting the striated muscle of the hypopharynx and upper third of the esophagus. As a result, there is loss of normal swallowing function and failure to protect the airway. Aspiration is more likely in those patients with extensive skin or muscle involvement given the associated myositis.

Respiratory Muscle Dysfunction

Hypercapnic respiratory failure requiring assisted ventilation, due to extensive myositis involving the respiratory muscles and diaphragm, is an uncommon event (5% prevalence). In those patients presenting with unexplained hypercapnic respiratory failure, polymyositis–dermatomyositis as well as demyelinating neuromuscular disorders should be considered. With less extensive involvement of these muscles, however, there is a reduction in cough generation and the potential for the development of hypostatic pneumonia and atelectasis due to mucus plugging. Weakness can also cause a restricted physiologic defect with resulting tachypnea and dyspnea in the face of a normal diffusing capacity, normoxia, and hyperventilation. Respiratory muscle dysfunction as the cause of restrictive lung disease can best be demonstrated by measurement of the maximal pressure generated during both phases of the respiratory cycle. Sequential measurements are useful for monitoring the disease course and response to treatment.

Interstitial Lung Disease

The prevalence of interstitial lung disease in polymyositis–dermatomyositis ranges from 5% to 30%.[76,77] The incidence is significantly higher in certain populations. In Japan, it approached 40% to 80% in one series. As in the other collagen vascular diseases, the use of bronchoalveolar lavage and HRCT for screening increases the documented incidence. In those screened with HRCT imaging, the incidence approaches 78% within 3 years of diagnosis.[78]

Although UIP was previously reported to be the predominant histologic type of interstitial lung disease seen in polymyositis–dermatomyositis, NSIP with organizing pneumonia now appears to be most common, based on the revised classification system for idiopathic interstitial pneumonias. DAD, organizing pneumonia, and diffuse alveolar hemorrhage secondary to pulmonary capillaritis also may occur.[79] All forms of interstitial lung disease may precede, appear simultaneously with, or follow the muscle or skin manifestations. There is no relationship between interstitial lung disease and the extent of muscle or skin disease, the level of creatinine phosphokinase elevation, or the presence of serum rheumatoid factor or antinuclear antibodies. There is, however, a relationship between interstitial lung disease and a serum antibody directed against tRNA-synthetases, the most common of which is known as anti–Jo-1.[80] This antibody appears in 25% of patients with polymyositis–dermatomyositis in total, but in 50% of patients with interstitial lung disease and in 13% of patients without lung disease. Depending on which tRNA-synthetase antibody is present, different clinical phenotypes may occur with varying degrees of myositis and lung involvement.[81,82] Antinuclear antibodies are detected in up to 80% of patients. Different categories of autoantibodies may provide guidance into prognosis, potential organ involvement, or perhaps comorbid rheumatologic conditions. In several retrospective analyses, the presence of a (+) antimelanoma differentiation-associated gene 5 (anti-MDA5) was associated with a poorer prognosis compared with the anti–aminoacyl-tRNA synthetase (ARS) antibody-positive subjects (anti–Jo-1, anti–PL-12, OJ, EJ, PL-7, PL-12, KS, Zo, and Ha) or those without myositis-associated antibodies and ILD. Anti-MDA5 constitutes 30% of patients with dermatomyositis and is associated with a higher percentage of rapidly progressive patients and poorer 5-year survival (50%) despite treatment with immunosuppressive therapy. Myositis-specific autoantibodies, namely ARS, are associated with a more favorable response to immunosuppressive therapy (60%) and a 5-year survival of 97%. Patients with myositis-associated ILD without seropositivity were similar in their clinical course to the ARS group, with a 5-year survival of 91%.[83,84]

All forms of interstitial lung disease in polymyositis–dermatomyositis are more common in women. Several clinical syndromes occur and are associated with the underlying interstitial lung disease. The most common presentation is chronic cough and progressive dyspnea due to NSIP with varying degrees of fibrosis.[85] Digital clubbing is rarely seen. Chest radiographs demonstrate reticulonodular infiltrates, and with disease progression there is a reduction of the lung volume and the development of radiographic honeycomb lung and pulmonary hypertension. Physiologic testing indicates a restrictive pattern with a low diffusing capacity. Response to treatment depends upon the underlying histology, the more cellular disease being more responsive. In corticosteroid-resistant patients, cyclophosphamide, cyclosporine, tacrolimus, mycophenolate mofetil, intravenous immunoglobulins, and rituximab have been used with efficacy.[86]

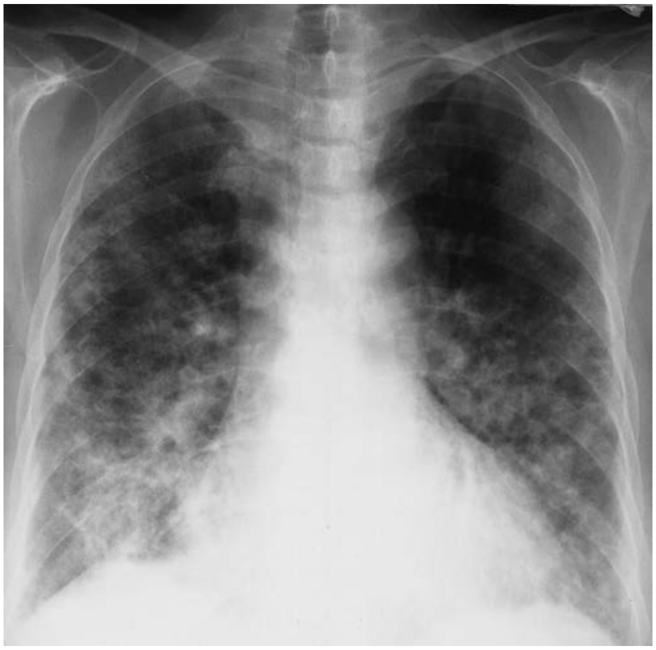

Figure 58-20 Organizing pneumonia in a patient with polymyositis–dermatomyositis and acute symptoms. Chest radiograph demonstrating diffuse patchy alveolar infiltrates.

In polymyositis–dermatomyositis, an acute pulmonary presentation with a clinical and radiographic picture reminiscent of a diffuse infectious pneumonia may occur and is associated with a poorer prognosis. The underlying lesion is DAD. Severe respiratory failure occurs, and recovery is unusual despite aggressive anti-inflammatory and immunosuppressive therapy. Organizing pneumonia may have either an acute or subacute presentation (Fig. 58-20). The differentiation from DAD becomes important because of the marked disparity in treatment outcome and survival. In organizing pneumonia, corticosteroid responsiveness with or without an additional agent is the rule rather than the exception. Diffuse alveolar hemorrhage due to pulmonary capillaritis also may occur.[87] This complication appears simultaneously with the onset of the muscle disease. Hemoptysis may or may not be present. As with other forms of pulmonary capillaritis, immunosuppression with corticosteroids and cyclophosphamide is utilized and been efficacious.

MIXED CONNECTIVE-TISSUE DISEASE: CLINICAL FEATURES

Patients with mixed connective-tissue disease have features of SLE, polymyositis–dermatomyositis, and scleroderma. Mixed connective-tissue disease is characterized by elevated titers of a specific antinuclear antibody directed against nuclear ribonucleoprotein (anti-RNP). Because of the similarity of mixed connective-tissue disease to the aforementioned collagen vascular diseases, pleuropulmonary complications are frequent, occurring in 20% to 80% of cases.[88,89]

Pleural Disease

Although pleurisy has been reported to occur in 40% of cases, pleural effusions are uncommon, appearing in approximately 5% of cases.[90] Effusions have been characterized as exudative in nature, but limited information is available in the literature.

Pulmonary Vascular Disease

Pulmonary hypertension may be caused by recurrent pulmonary emboli, hypoxic vasoconstriction secondary to interstitial lung disease, or plexogenic arteriopathy, as occurs in SLE and scleroderma. This is a significant problem for these patients; however, the incidence is unknown but may be less common than previously believed.[91] These patients, primarily women, present with dyspnea and fatigue. They have normal chest radiographs except for pulmonary arterial enlargement and an isolated reduction in the diffusing capacity for carbon monoxide. The prognosis in pulmonary hypertension secondary to mixed connective-tissue disease is similar to that noted in pulmonary hypertension seen in scleroderma and SLE. In contrast to patients without pulmonary arterial hypertension, 5-year survival is decreased from 96% to 73%.[92,93]

Medium-sized pulmonary artery vasculitis has been reported in mixed connective-tissue disease, with evidence suggesting immunologic-mediated injury with deposition (IgG, C_3) in the vascular walls. Circulating lupus anticoagulant (antiphospholipid syndrome) may also complicate the course of patients with mixed connective-tissue disease, predisposing them to thromboembolic disease.[94] It is in these patients that recurrent small pulmonary emboli may mimic the clinical picture of idiopathic pulmonary hypertension.

Aspiration Pneumonia

Patients with mixed connective-tissue disease, presenting with predominant features of scleroderma or polymyositis–dermatomyositis, are predisposed to esophageal dysmotility and dilatation, which can be a significant problem leading to reflux esophagitis and recurrent aspiration pneumonia. The presence of radiographic evidence of ILD closely associates with esophageal dilation and motor dysfunction, suggesting a common pathobiology.[95]

Respiratory Muscle Dysfunction

In those patients with features of polymyositis–dermatomyositis, an inflammatory myositis with respiratory muscle involvement may lead to hypercapnic respiratory failure or a restrictive lung disease with the development of hypostatic pneumonia.

Interstitial Lung Disease

The incidence of interstitial lung disease in mixed connective-tissue disease is increased in comparison to other collagen vascular diseases, with greater than 50% of patients having abnormal high-resolution CT imaging abnormalities.[96] The histologic pattern of NSIP and/or UIP are noted, both of which may progress to honeycomb lung, particularly in those patients with the features of scleroderma. As with the other connective-tissue diseases, this interstitial lung disease manifests as progressive dyspnea, bibasilar reticulonodular infiltrates on chest radiograph, and physiologic parameters with low lung volumes and a reduction in the diffusing capacity for carbon monoxide.

Diffuse alveolar hemorrhage has been reported in a few cases of mixed connective-tissue disease and is similar in presentation to that in SLE. It is assumed that the histology is one of either bland pulmonary hemorrhage or pulmonary capillaritis but remains unknown.[97]

SJÖGREN SYNDROME

Sjögren syndrome refers to a triad of xerophthalmia, xerostomia, and polyarthritis. This autoimmune exocrinopathy is characterized by lymphocytic infiltration of the lacrimal and salivary glands.[98] A primary form, occurring in the absence of another collagen vascular disease, and a secondary form, associated with one of the other collagen vascular diseases, most frequently RA, exist.[99] A strong female predominance exists in Sjögren syndrome (90%). A positive rheumatoid factor (95%) and antinuclear antibodies in a speckled pattern (80%) are to be expected, as well as positive tests for antibodies to extractable nuclear antigens (anti-SSA, anti-SSB), which are specific for the primary form of the syndrome.

Airway Disease

Lymphocytic infiltration and destruction of airway mucus glands result in desiccation of the tracheobronchial tree in Sjögren syndrome.[100] Patients may develop hoarseness, cough, inspissation of secretions resulting in luminal obstruction and atelectasis, recurrent pneumonias, and bronchiectasis. There is a high incidence of obstructive ventilatory dysfunction in these patients, secondary to follicular bronchiolitis. Obliterative bronchiolitis, constrictive bronchiolitis, and bronchiolectasis also have been reported.

Interstitial Lung Disease

In primary Sjögren syndrome, patients present with a nonproductive cough, dyspnea on exertion, or asymptomatic radiographic abnormalities. As occurs in the lacrimal and salivary glands, interstitial lung disease in these patients is the result of lymphocytic infiltration of the lung parenchyma. This occurs in two forms, lymphocytic interstitial pneumonitis and, less commonly, pseudolymphoma. Both lesions have the potential for lymphomatous conversion. Lymphocytic interstitial pneumonitis is an interstitial lung disease in which cough, dyspnea, and restrictive physiology manifest. Because lymphocytes may also infiltrate the alveolar spaces as well as the interstitium, the radiologic studies indicate mixed alveolar and interstitial infiltrates. In a subset of patients, variably sized cystic lesions with associated ground glass may be the only radiographic abnormality (Fig. 58-21). The development of pleural effusions or the appearance of hilar or mediastinal adenopathy should be investigated further, as it may suggest a malignant transformation to a lymphoma. Lymphocytic interstitial

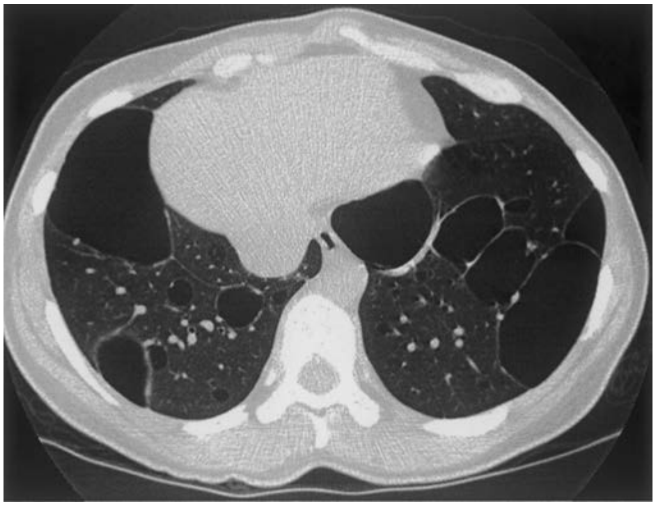

Figure 58-21 Multiple cysts of varying sizes scattered throughout both lungs in a patient with Sjögren syndrome and lymphocytic interstitial pneumonia.

pneumonia is responsive to anti-inflammatory agents such as corticosteroids. Occasionally, cytolytic therapy, such as azathioprine or cyclophosphamide, is required but remains of unproven benefit. Cyclosporine has also been recommended as an additional agent in corticosteroid-resistant cases. Rituximab, an anti-CD20 monoclonal antibody, may be beneficial in selected patients but further controlled studies are required to better assess its efficacy in primary Sjögren syndrome.[101] While the majority of patients will respond to immunosuppressive therapy, a subset of patients progress to fibrotic lung disease with honeycomb change.

Pseudolymphoma is a tumor-like proliferation appearing as single or multiple masses on the chest radiograph. It is often difficult to distinguish from a malignant lymphoma, and it has been suggested that pseudolymphoma, which is considered to be a localized form of lymphocytic interstitial pneumonitis, is a premalignant lesion.[102] When associated with a monoclonal gammopathy, malignant transformation to lymphoma is suggested.[103]

Interstitial lung disease occurs more commonly in the secondary forms of Sjögren syndrome and most likely represents a complication of the associated collagen vascular disease.[2] The histologic pattern in secondary Sjögren syndrome mimics that seen in rheumatoid arthritis, with NSIP, UIP, and organizing pneumonia reported. UIP is uncommon in the primary form of Sjögren syndrome.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is one of the seronegative spondyloarthropathies that may eventually result in fixation of the chest wall and a mild to moderate restrictive lung disease. Muscular involvement, in contrast to polymyositis–dermatomyositis, does not occur and diaphragmatic function is preserved, limiting ventilatory failure given the preserved respiratory muscle function.

The incidence of interstitial lung disease complication is reportedly less than 2%.[104] In contrast to the other collagen vascular diseases that primarily affect the basilar portion of the lung, ankylosing spondylitis has a predilection for the upper lung zones, only appears late in the course of the chronic spondylitis, and never precedes it.[105] Interstitial lung disease often appears as fibrocystic disease on the chest radiograph (Fig. 58-22) and is difficult to distinguish from apical lung infections such as tuberculosis. Histologically, it is a fibrosing process with cystic formation. Progressive dyspnea and cough are the predominant symptoms, and treatment with corticosteroids is ineffective and therefore not suggested. Etanercept may afford patient a short-term benefit with improvements in spinal mobility and pulmonary physiology.[106] The most serious complication of this apical fibrocystic disease is infection with invasive *Aspergillus* species as well as atypical mycobacteria. Further, saprophytic colonization of the cysts by *Aspergillus* species (aspergilloma) may induce life-threatening hemoptysis.

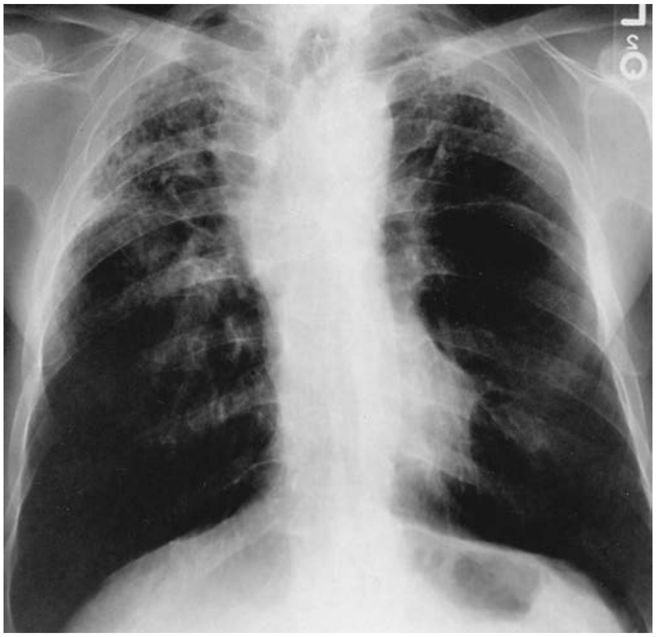

Figure 58-22 Ankylosing spondylitis. Chest radiograph demonstrating bilateral upper-zone fibronodular infiltrates.

INTERSTITIAL PNEUMONIA WITH AUTOIMMUNE FEATURES

Autoimmune signs or symptoms occur in a significant proportion of patients diagnosed with an idiopathic interstitial pneumonia but fail to meet established diagnostic criteria for a specific connective tissue disease. Interstitial lung disease may be the forme fruste of an underlying connective tissue disease by months or even years. A European Respiratory Society/American Thoracic Society Task Force established research criteria to better define this challenging clinical situation, termed *interstitial pneumonia with autoimmune features (IPAF)*.[107] Three distinct clinical domains were delineated: (1) specific extrathoracic features (signs or symptoms), (2) serologic abnormalities with specific autoantibodies, and (3) morphologic domain with radiographic, pathologic, and physiologic features. The classification established a framework to define a unique group of individuals with idiopathic interstitial pneumonia and enable prospective studies to determine the natural history and clinical implications of IPAF. In most connective tissue diseases other than rheumatoid arthritis, an NSIP radiographic and pathologic pattern is most common. Data from one retrospective series suggest a UIP radiographic pattern is more common in IPAF (65%) in contrast to NSIP.[108] Acute exacerbations may be less frequent in IPAF and more responsive to anti-inflammatory therapy.[109,110] These observations raise several important questions that need to be explored rigorously: Do individuals with IPAF develop a classifiable connective tissue disease? Is the natural history of disease different from other idiopathic interstitial pneumonias? In contrast to patients with idiopathic pulmonary fibrosis, should anti-inflammatory or immunologic therapies be considered in patients with IPAF? Suggestions from retrospective and small, single-center series have been delineated but more robust, multicenter, prospective investigations are necessary to continue define IPAF, its natural history, and appropriate treatments.

CHAPTER 59

Pulmonary Langerhans Cell Histiocytosis

Sergio Harari
Davide Elia
Joel Moss
Abdellatif Tazi

INTRODUCTION

Histiocytosis or histiocytic disorders are characterized by abnormal function and accumulation or differentiation of specific cells, thought to be derived from dendritic cells (DCs) or the monocyte–macrophage lineage.[1] Among this group of diseases, Langerhans cell histiocytosis (LCH) is the most common and is characterized by an activation of the MAPK-ERK pathway, driven by various molecular abnormalities in this pathway, particularly the canonical *BRAF*^{V600E} mutation in about half of LCH lesions.[2,3] Importantly, the cell-specific gene expression signature in Langerin (CD207)-positive cells within specific lesions has shown that LCH cells are more consistent with immature myeloid dendritic cell precursors than with Langerhans cells.[4]

LCH clinical manifestations range from mild, with a single organ involvement, to disseminated life-threatening presentations. Depending on the sites involved and severity, the entity now referred to as LCH has been previously defined as eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease. A more recent and simplified classification categorizes LCH based on single-organ or multisystem involvement.[2] The systemic presentations of the disease are usually associated with a worse prognosis, particularly when the so-called risk organs (i.e., liver, spleen, and hematopoietic system) are involved. This severe form of LCH is encountered mainly in young children and more rarely in older patients.[2,5]

Lung involvement in LCH may occur less commonly as a part of a multisystemic disease, or most frequently as a single, primary involved organ. In this latter instance, the disease is usually called *pulmonary LCH (PLCH)*.[6] PLCH belongs to the spectrum of diffuse cystic lung diseases.[7] It is characterized by the infiltration and destruction of bronchiolar walls by specialized dendritic cells organized into granulomas.[6] However, lung interstitium and pulmonary vasculature may also be involved by the pathologic process to varying extents, resulting in diverse phenotypes. Although PLCH is classically considered as a distinct entity in which smoking habit plays a role, the discovery of MAPK-ERK mutations in this group of patients suggests a biologic similarity with other subtypes of LCH.[8]

EPIDEMIOLOGY

LCH occurs sporadically, although rare familial cases and pairs of homozygous twins have been reported. The exact incidence and prevalence of PLCH are unknown. Early studies with a confirmed histologic diagnosis highlighted the rarity of the disease, which accounted for 3% to 5% of adult patients with diffuse infiltrative lung diseases.[6] However, these reports most probably underestimated the true prevalence of PLCH. Indeed, with the wide use of chest high-resolution computed tomography (HRCT) in the routine evaluation of patients, increased numbers of PLCH cases were identified; lung biopsy is not systematically performed, and some patients exhibited no symptoms or experienced spontaneous remission.[6] Occupational or geographic predisposition has not been reported. The most striking epidemiologic feature of PLCH is that it occurs almost exclusively in smokers or ex-smokers (>90% of cases).[6] The role of smoking in triggering PLCH is highlighted by the finding that most children with systemic LCH who developed PLCH in adolescence or adulthood started to smoke before onset of the disease.[6] In addition to cigarette smoking, about 20% inpatients of the French national registry are also cannabis users (Tazi, personal observation).

A peak of incidence has been observed in the second to fourth decade of life, with no gender predominance, although females may develop PLCH at slightly older ages.[6] Isolated LCH lung involvement has been rarely reported in children. PLCH seems to occur mostly among the Caucasian population, with very few cases reported in Blacks or African-Americans for unknown reasons. The disease has also been described in patients of Asian descent.[9,10]

LCH, including PLCH, is associated with increased risk of various malignancies, such as hematologic and solid tumors, including lung cancer. The type and incidence of these malignancies widely vary according to the LCH presentation (single vs. multisystem), the selected population, and the treatment (chemotherapy or radiation) the patients had eventually received for their LCH.[2,6,11–14] Cigarette smoke and tobacco compounds may play a role in the development of some of these tumors, particularly lung carcinomas. However, given the complexity of factors involved in the pathogenesis of both cancers and PLCH, shared host-related predisposing factors have been hypothesized.[14,15]

CLINICAL PRESENTATION

Clinical manifestation of PLCH may be silent or associated with nonspecific respiratory symptoms.[6] Patients come to medical evaluation after incidental findings on screening chest imaging (5%–35%), following spontaneous pneumothorax (10%–20%), or because of respiratory or constitutional symptoms. Cough, mostly not productive (50%–70%), dyspnea (40%–60%), and chest pain (10%–20%) are the most common respiratory symptoms described by patients, sometimes associated with systemic manifestations such as fatigue, weight loss, and fever in 10% to 20% of cases. Hemoptysis has been occasionally reported but should prompt a search for superimposed infection (rarely, *Aspergillus* in a lung cyst) or tumor.

In some cases, symptoms may be related to the presence of extrathoracic involvement. Localized pain and/or pathologic bone fractures may be related to the infiltration of the bone with osteolytic lesions (15%–20%), generally solitary and affecting the flat bones.[6,9,16] Skeletal involvement may precede pulmonary manifestations. Polyuria–polydipsia syndrome may occur due to pituitary stalk involvement with diabetes insipidus (5%–15% of patients) and more rarely skin involvement, usually as erythematous, maculopapular, or nodular lesions. The scalp is often involved by characteristic seborrheic and crusted lesions.[17]

In the absence of pneumothorax or extrathoracic findings as described, physical examination is usually unremarkable. At chest examination, crackles are uncommon as is digital clubbing. Manifestations of pulmonary hypertension are seen in advanced stages. Routine laboratory studies are usually unrevealing. A mild increase in peripheral neutrophil counts and blood inflammatory markers may be observed, but the peripheral eosinophil count is normal.[18]

PATHOGENESIS

The molecular basis, histopathologic findings, and role of tobacco smoking in PLCH are discussed below.

MAPK Pathway Activation

Although the pathogenesis of PLCH is still not fully understood, important progress has been made.

A critical breakthrough in the understanding of LCH pathogenesis was the identification a decade ago of recurrent somatic *BRAF*$^{\text{V600E}}$ mutations in approximately half of LCH lesions originating from different tissues, including the lung, supporting the hypothesis of a clonal/neoplastic origin of the disease.[19] *BRAF*$^{\text{V600E}}$ is a proto-oncogene mutation localized in the canonical mitogen-activated kinase (MAPK) pathway. Physiologically, MAPK activation results from the binding of an extracellular ligand to the tyrosine kinase receptor (TKR), inducing the activation of RAS thorough its transformation from Ras-GDP to Ras-GTP, leading downstream to RAF, resulting in the phosphorylation of MAPK kinase (MEK1/2) and ERK (extracellular signal-regulated kinase), which are responsible for the phosphorylation of a number of substrates involved in different cellular processes.[3,20] Somatic *BRAF*$^{\text{V600E}}$ mutation results in a modified kinase domain that is associated with constitutive activation of the MAPK pathway, thus deregulating the control of cell differentiation and survival (Fig. 59-1). *BRAF*$^{\text{V600E}}$ mutation has been detected in 30% to 75% of LCH cells in systemic LCH lesions[2,3] and in 30% to 50% of patients with PLCH.[8,21–24] This mutation is also observed in other tumors, such as malignant melanomas, and in almost all cases of hairy cell leukemia,[25] as well as in benign nevi.[26]

In several patients affected by multisystem LCH, particularly with risk organ involvement, and in a small group of cases with a single-system disease, circulating cell-free DNA *BRAF*$^{\text{V600E}}$ has been detected, allowing for diagnosis without the need to obtain a tissue sample.[27–29] Less frequently, this mutation has been observed in circulating CD11c+ precursors, CD1c+ myeloid dendritic cells, and CD14+ monocytes, as well as in bone marrow progenitors in patients affected by multisystem LCH.[30–32]

The key role played by MAPK pathway activation in the pathogenesis of the disease has been further supported by the finding of an independent activation of this pathway even in absence of the *BRAF*$^{\text{V600E}}$ mutation.[19]

MAP2K1 gene mutations have been identified in *BRAF*-wild-type LCH lesions and in 8.6% to 40% of biopsies from different tissues obtained from pediatric and adult LCH patients.[3] In LCH lesions, the presence of *MAP2K1* mutations is mutually exclusive of the presence of the *BRAF*$^{\text{V600E}}$ mutation. These mutations are able to promote the activation of ERK and are considered to be driver mutations in the disease.[8,22,33–40] Other MAPK alterations have been described in several cases and small case series, such as non-V600E *BRAF* mutations, *BRAF* deletions, *BRAF* duplications, and *ARAF-CRAF* mutations.[8,34,41–46] Additionally, in adult PLCH, *NRAS* mutations occur at a low frequency concurrently with the *BRAF*$^{\text{V600E}}$ mutation in a significant subset of cases and are carried by different clones within the lesion.[47] Overall, MAPK alterations are present in 75% to 93% of LCH lesions.[3,8,42,45] Based on these findings, LCH is considered an inflammatory myeloid neoplastic disorder, driven by mutations activating the MAPK pathway.[2] Furthermore, molecular alterations of the MAPK pathway have also been identified in most lesions of Erdheim-Chester disease (ECD), a non–Langerhans cell histiocytosis, and have led to a revision of the classification of histiocytic disorders[42,46] in which LCH and ECD are now grouped together.[1]

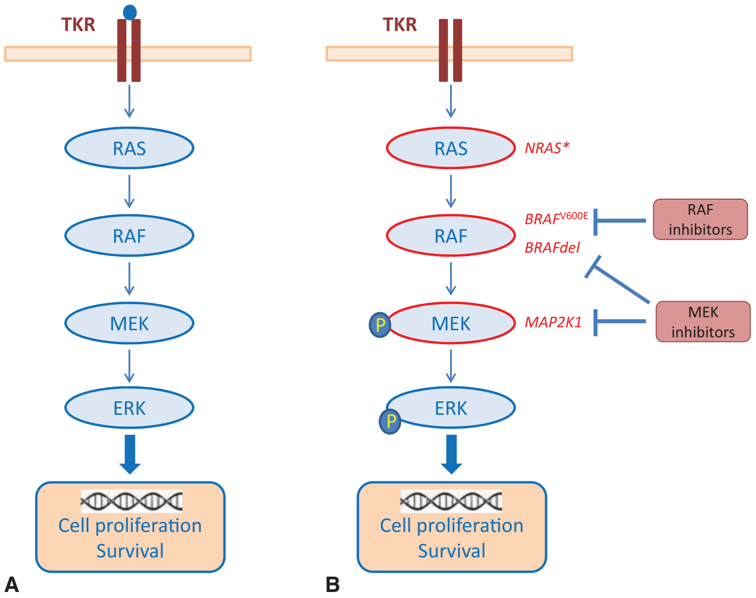

Figure 59-1 Schematic representation of the MAPK pathway and the principal molecular alterations identified in LCH lesions. **A.** In physiologic state, the RAS-RAF cascade is activated following the binding of an extracellular ligand (growth factors, cytokines) to the tyrosine kinase receptor (TKR) leading to phosphorylation (P) of MEK and ERK proteins. Ultimately, various processes are regulated by this pathway, including cellular proliferation and survival. **B.** The presence of mutations at different steps of the MAPK pathway induces its constitutive activation, without ligand binding on the TKR. The main genomic alterations identified in LCH lesions, including PLCH, are indicated. These alterations can be targeted by BRAF and MEK inhibitors. *Isolated *NRAS* mutations are rarely identified in PLCH, and they are more frequently observed at a low allele frequency concurrently with the *BRAF*$^{\text{V600E}}$ mutation in the same specimen. *BRAF*del, *BRAF* deletion; ERK, extracellular signal-regulated kinase; LCH, Langerhans cell histiocytosis; MAPK, mitogen-activated protein kinase; MEK, MAPK kinase; PLCH, pulmonary Langerhans cell histiocytosis; TKR, tyrosine kinase receptor.

PLCH Lesions

Accumulation of a large number of CD1a+/CD207+ cells in loosely formed bronchiolocentric granulomas, resulting in airspace invasion, cavitation, and consequent destruction of lung parenchyma, is a peculiar feature of PLCH.[6,23] Very few LCH cells proliferate in the lesions in PLCH granulomas, and these cells appear to be less sensitive to apoptosis.[6] The presence within and around PLCH lesions of local growth factors, granulocyte-macrophage colony-stimulating factor (GM-CSF), and chemokines (CCL20 and CCL2) suggests their role in the differentiation of myeloid hematopoietic precursors, recruited from circulating peripheral blood, in LCH lesions.[6,48] Differentiation of precursor cells residing locally in the involved tissues also is possible. It is possible that MAPK pathway activation can lead to activation of senescence pathways in CD1a+ myeloid cells that then proceed to infiltrate the lung.[24] This oncogene-induced senescence is a mechanism by which cell cycle arrest and inflammation may be perpetuated in PLCH. It is also possible that such cellular senescence may be driven by cigarette smoke exposure. The various cytokines locally produced, local neoangiogenesis, and the action for cell adhesion molecules help in the accumulation of LCH cells, T lymphocytes, and inflammatory cells.[6,48]

The ability of PLCH granulomas to destroy the bronchiolar wall and remodel the surrounding lung parenchyma may be related to a peculiar characteristic of CD1a+ cells found in the granulomas. These cells show different types of markers of membrane maturation, similar to those usually found on the surface of dendritic cells after exposure to various pathogens. However, a significant proportion of lymphocytes infiltrating the lesions are regulatory T cells,[49] and the

CD1a+ cell-mediated cytotoxic action of T lymphocytes seems to be impaired.[6] For this reason, other mechanisms involved in the tissue destruction have been hypothesized, such as locally secreted metalloproteinases.[6] In addition, activation of the Notch1 signaling pathway has been shown to be at least partly responsible for the specific phenotypic and functional profile of LCH cells.[4]

■ Role of Smoking

The role played by tobacco smoking in the pathogenesis of the disease is supported by a number of findings. For example, it has been observed that smoking induces changes in the epithelium of distal bronchioles and an accumulation of CD1a+ cells in healthy smokers, as well as in the lungs of patients with different pulmonary diseases and in murine models.[6] In addition, tobacco smoke leads to the production of local cytokines, promoting the differentiation and activation of dendritic cells in PLCH lesions.[6] Tobacco smoke also promotes the survival of dendritic cells via antiapoptotic mechanisms. Levels of glycoprotein osteopontin, secretion of which is increased by nicotine, are higher in the bronchoalveolar lavage (BAL) fluid of smoking patients with PLCH compared with healthy smokers.[6] A chemotactic effect on monocytes/macrophages and dendritic cells is induced by osteopontin, and the development of PLCH-like lesions has been induced by its overexpression in murine models.[6] Recently, a *BRAF*^{V600E} transgenic murine model elegantly showed that exposure of mice to cigarette smoke was necessary to induce lung lesions similar to those observed in PLCH.[50]

HISTOPATHOLOGY

The accumulation LCH cells (sharing features of LCs) into loosely aggregated granulomas, preferentially located in and destroying the wall of distal bronchioles, is the main histologic feature of PLCH[6,23] (Fig. 59-2). The granulomas may also extend into adjacent alveolar structures. A pale-staining cytoplasm and large convoluted nucleus is characteristic of these cells, and the classic pentalaminar cytoplasmic inclusion known as Birbeck granules can be observed by electron microscopy. The LCH cell surface is characterized by the presence of CD1a antigen and Langerin (CD207), a type II mannose lectin that is constitutively associated with Birbeck granules—both markers not observed in other histiocytic cells (Fig. 59-2). Although LCH cells react with anti-S-100 antibody, this feature is not specific, as it has been observed in other cell types (e.g., neuroendocrine cells, some macrophages) and should not be used for LCH diagnosis.

A mixture of LCH cells, eosinophils, lymphocytes, and some giant cells are localized around the smaller bronchioles in the early stages of the disease. These cells seem to invade the bronchiole, destroying the bronchial wall. Furthermore, the lesions affect pulmonary arterioles and venules. For this reason, the disease is described as showing a bronchovascular distribution.[6,23]

Pseudo-desquamative interstitial pneumonia (characterized by the accumulation of alveolar macrophages in the alveolar parenchyma between PLCH lesions) and respiratory (smoker's) bronchiolitis (with pigmented macrophages filling the lumen of bronchioles and the surrounding alveolar spaces) also have often been found on

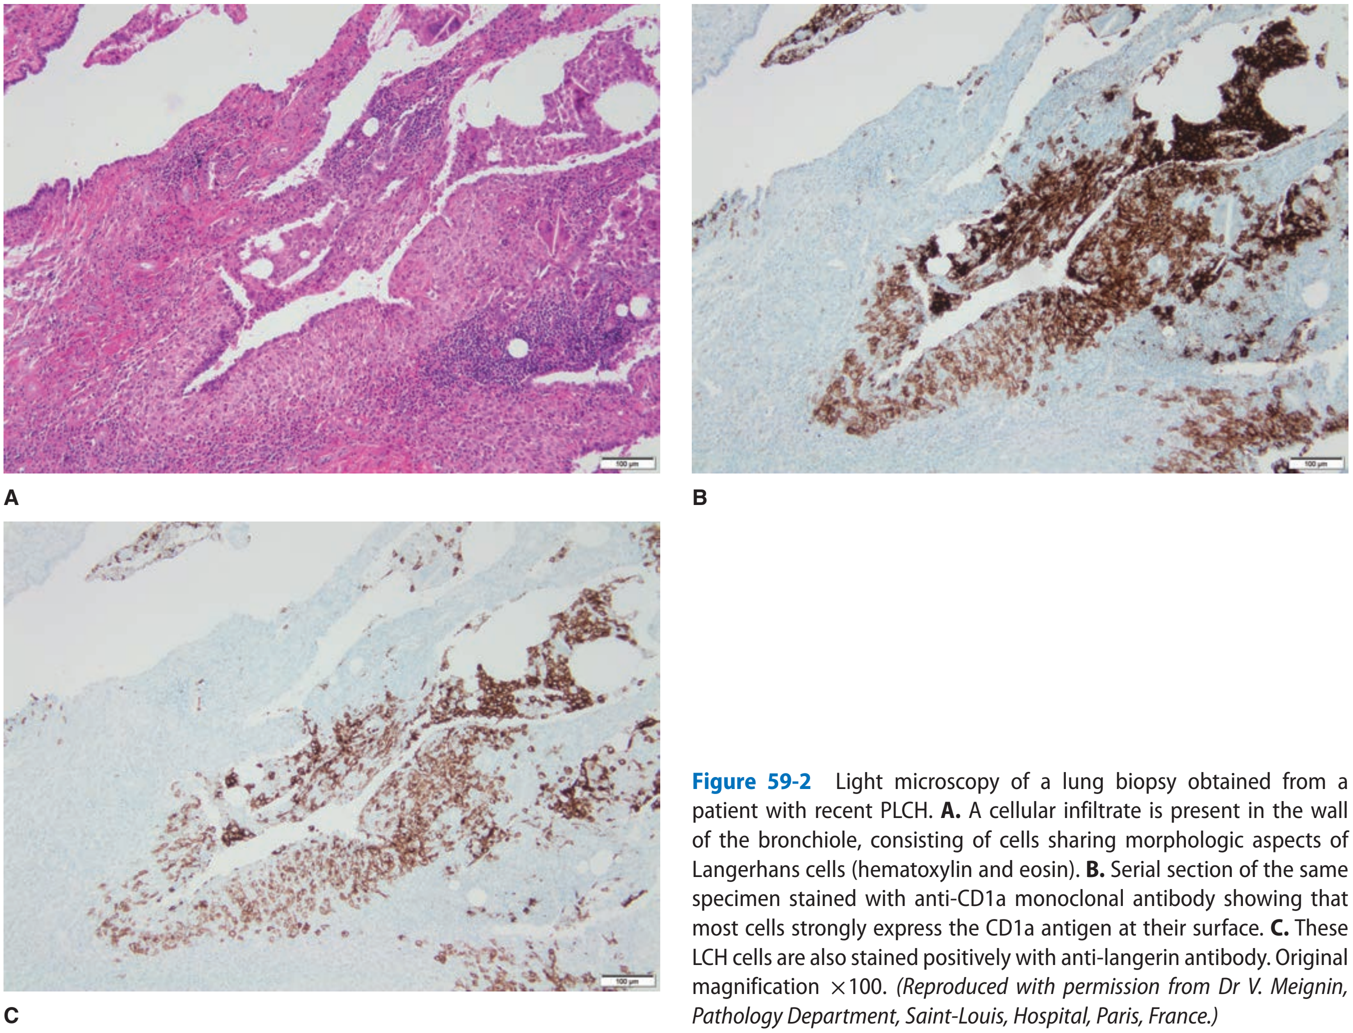

Figure 59-2 Light microscopy of a lung biopsy obtained from a patient with recent PLCH. **A.** A cellular infiltrate is present in the wall of the bronchiole, consisting of cells sharing morphologic aspects of Langerhans cells (hematoxylin and eosin). **B.** Serial section of the same specimen stained with anti-CD1a monoclonal antibody showing that most cells strongly express the CD1a antigen at their surface. **C.** These LCH cells are also stained positively with anti-langerin antibody. Original magnification ×100. *(Reproduced with permission from Dr V. Meignin, Pathology Department, Saint-Louis, Hospital, Paris, France.)*

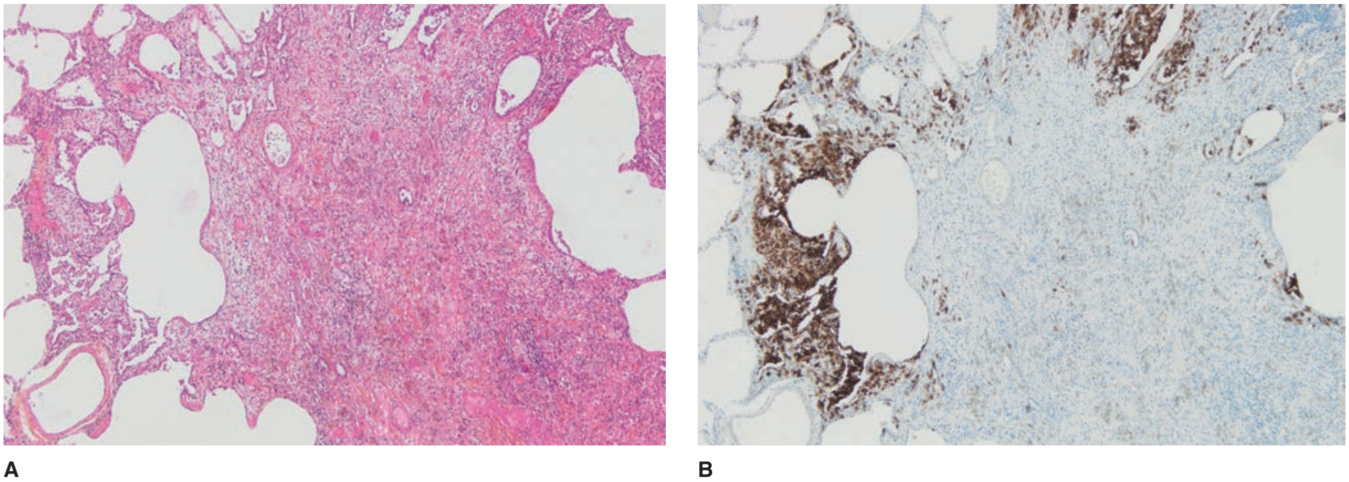

Figure 59-3 Light microscopy of a PLCH lung biopsy. **A.** The lesion is centrally cavitated and surrounded by an inflammatory infiltrate (hematoxylin and eosin). **B.** This cellular infiltrate is positively stained with anti-CD1a monoclonal antibody on a serial section. Original magnification ×40. *(Reproduced with permission from Dr V. Meignin, Pathology Department, Saint-Louis, Hospital, Paris, France.)*

lung biopsy.[6,23,51] In addition, intraluminal fibrosis is often present. Three-dimensional reconstruction of the lesions from serial sections shows that PLCH lesions are elongated, sheath-like structures of variable diameter that extend proximally and distally along bronchioles, without necessarily having spherical morphology.[6,23]

The pathologic features of PLCH change over time, and lesions of various ages are often found in the same lung biopsy specimen. Destruction of the bronchiolar epithelium occurs early in the disease process, such that the bronchiole-centered development of the lesions may be difficult to confirm on a single section. Although early lesions often seem cavitated, the cavity is the residual lumen of the bronchiole destroyed by the granulomatous reaction and does not result from tissue necrosis (Fig. 59-3). With progression of the lesions, the numbers of CD1a+ cells decrease, while inflammatory cells associated with lymphoid aggregates persist; they are subsequently replaced by either fibrosis in the form of a characteristic stellate scar, or contiguous and confluent cystic cavities surrounded by a fibrous ring. Traction emphysema contributes to the cystic appearance of advanced lesions.

IMAGING

The appearance of PLCH on routine chest radiographs, chest CT scans, and PET imaging is described below.

Chest Radiograph

In most cases, chest radiograph in PLCH is suggestive, although rarely it is normal at the time of clinical presentation. A typical PLCH radiographic pattern is characterized by the combination of ill-defined or stellate nodules (2–10 mm in size) associated with reticular opacities. Cysts are generally located in the middle to upper lobes, with sparing of the costophrenic angle.[6] Even though hyperinflation or reduced volume may be observed, total lung volume is generally normal. In advanced disease, chest radiograph may show an emphysema-like appearance. Hilar or mediastinal lymph node enlargement is rare in PLCH, and this finding should encourage further investigation for malignancy as a secondary diagnosis. Pleural effusion is not a feature of PLCH; occasionally pneumothorax can be detected at the time of the first chest radiograph, as can the presence of rib lesions.

Computed Tomography

Computer tomography (CT) images in PLCH are very characteristic, and their findings in a young smoker may be diagnostic. The CT is characterized by the combined presence of nodules, well or ill-defined, and cysts, varying in shape, size, and wall thickness[6,52] (Fig. 59-4). The distribution of the nodules is centrilobular, reflecting the bronchiole-centered development of PLCH lesions. The lesions

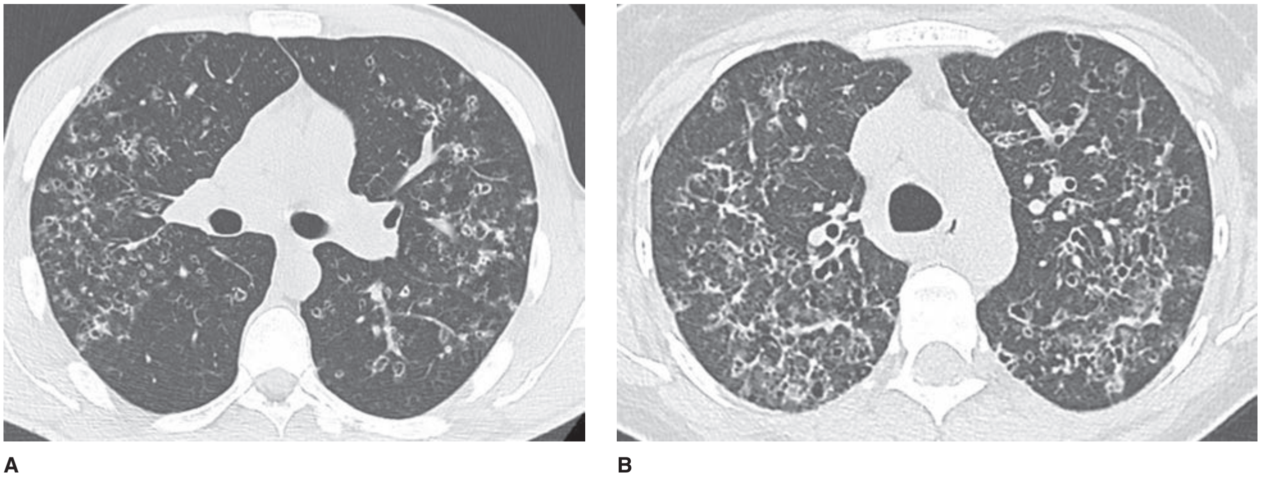

Figure 59-4 Representative HRCT images obtained from two patients with PLCH at an early stage. **A.** Characteristic association of nodules, cavitated nodules, and thick- and thin- wall cysts. **B.** More extensive similar HRCT pattern.

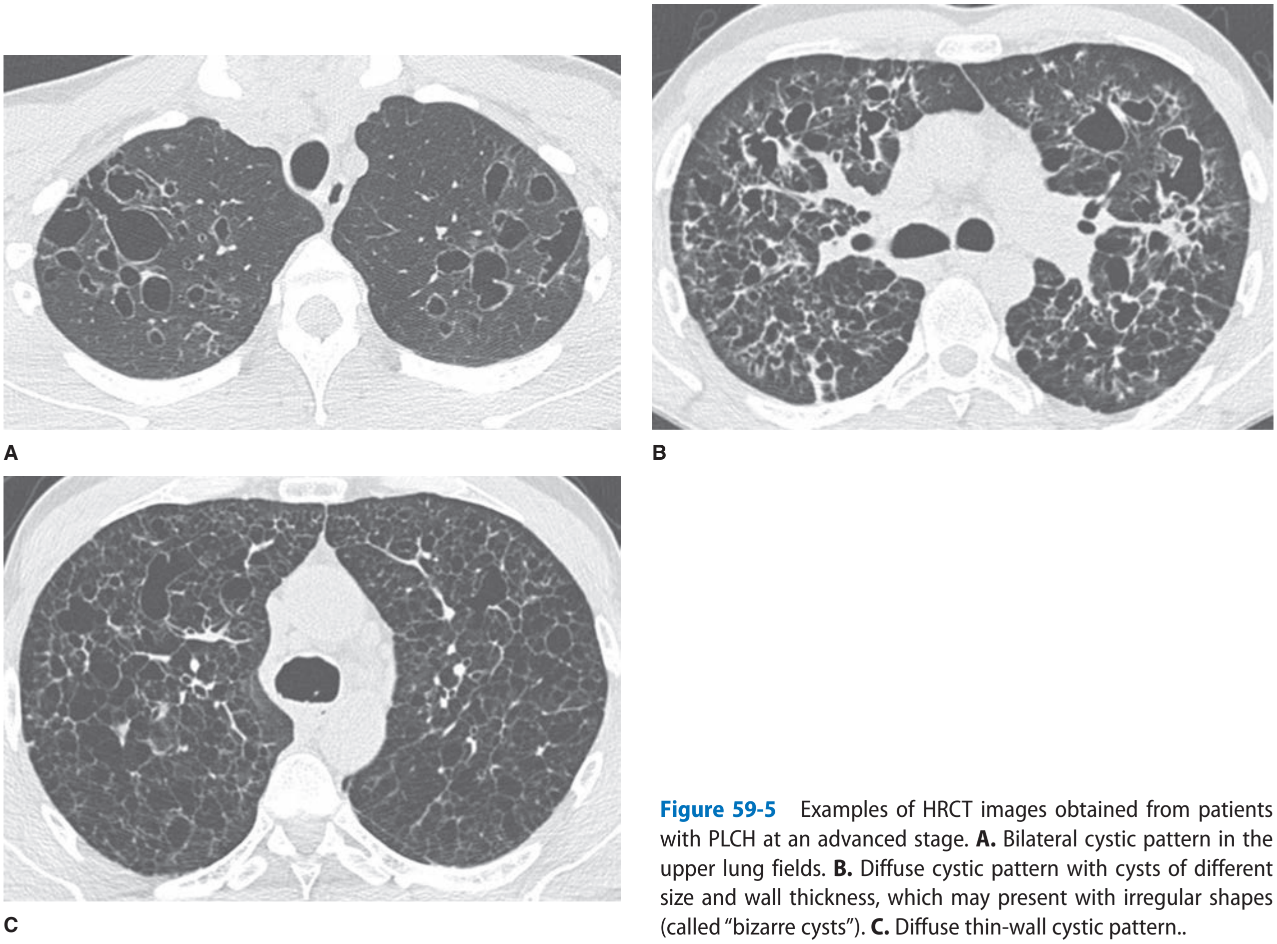

Figure 59-5 Examples of HRCT images obtained from patients with PLCH at an advanced stage. **A.** Bilateral cystic pattern in the upper lung fields. **B.** Diffuse cystic pattern with cysts of different size and wall thickness, which may present with irregular shapes (called "bizarre cysts"). **C.** Diffuse thin-wall cystic pattern..

are focal, being separated by parenchyma that appears normal. They usually predominate in the upper and middle lung fields, and tend to spare the basal portions of the lungs. As the disease evolves, cystic lesions become a predominant finding. Cysts vary in size and may coalesce to form irregular shapes ("bizarre cysts") (Fig. 59-5).

CT images reflect the histologic evolution of the disease, with serial chest CT demonstrating progression over time from nodular to cavitating to cystic lesions. Chest radiographs are not able to detect the degree of cyst formation. This may explain reports of "spontaneous remissions" before the routine use of thin-section CT.

Patients with a predominantly nodular HRCT pattern usually have minimal impairment in lung function, while worsening pulmonary function parameters correlates with the extent of cystic lesions. The utility of serial CT scanning in the monitoring and management of the disease is not clear.[52]

In rare cases, extensive ground-glass opacities on lung HRCT have been reported. This ground-glass pattern seems to reflect the extent of the histologic respiratory bronchiolitis-associated interstitial lung disease (RB-ILD)-like changes related to smoking that are observed in the lungs of these patients.[6]

■ PET Imaging

The role of 18-F-Fluorodeoxyglucose (FDG)-PET imaging in isolated PLCH needs to be better defined. It may be useful in quantifying disease activity, with positive scan results seen in patients with nodular, inflammatory lung disease, as well as those with thick-walled cysts.[53] Hypermetabolic PLCH nodules cannot be distinguished from malignant diseases. In patients with systemic manifestations, (FDG)-PET may provide valuable information regarding extrapulmonary involvement. It is still debated if PET-CT might be useful in predicting the natural course of the disease or the response of the disease to treatment.[53]

PHYSIOLOGIC TESTS

Physiologic evaluation in PLCH includes pulmonary function testing, exercise testing, and assessment for pulmonary hypertension.

■ Pulmonary Function Tests

Pulmonary function abnormalities are variable and depend on both the predominant anatomic lesions and the extent of cystic lesions on HRCT. Pulmonary function may vary from normal in the early stages (10%–15%) to an obstructive or restrictive or mixed pattern, according to the extension and the duration of the disease. The most common abnormality is represented by a reduction in the diffusing capacity for carbon monoxide ($\mathrm{DL}_{\mathrm{CO}}$), present in 80% to 90% of cases.[6,54] Disproportionately reduced $\mathrm{DL}_{\mathrm{CO}}$ is suggestive of a pulmonary vascular involvement.[6,52] Patients with a predominantly nodular HRCT pattern usually have minimal lung function alterations with an isolated reduction in $\mathrm{DL}_{\mathrm{CO}}$. The pulmonary function pattern frequently shows a reduction in vital capacity (VC), normal or increased residual volume (RV) with air trapping and preserved total lung capacity (TLC). A restrictive pattern (TLC <80% of predicted) is observed in approximately 10% of cases, with an obstructive pattern in 15% to 20%, typically in more advanced cases.[6,54] Reactive airway disease may be observed (noted in 10% of patients in a prospective study that included early-stage PLCH).[52] The extent of cystic changes in HRCT is correlated with lung function abnormalities, including airflow obstruction.[52] Blood gas levels at rest are normal in most cases, except in advanced stages.

Exercise Limitation

Patients affected by PLCH may complain of an impairment in activities of daily life and a worsening quality of life. This condition is associated with a decrease in maximum oxygen consumption ($\dot{V}O_{2peak}$) and a reduction of the 6-min walk distance. Pathophysiologic mechanisms underlying exercise limitation in these patients have been poorly investigated. Correlations between $\dot{V}O_{2peak}$ and the resting dead space/tidal volume ratio ($\dot{V}D/\dot{V}T$), residual volume, resting alveolar-to-arterial oxygen tension difference ($AaDO_2$), and DL_{CO} have been reported. Rolland-Debord et al. used cardiopulmonary exercise testing (CPET) to study a group of 62 subjects with PLCH; they found a reduction in $\dot{V}O_{2peak}$ in the majority (72%).[55] Patients with impaired aerobic capacity showed reduction in pulmonary function test values and increased $AaDO_2$. Furthermore, they presented with increased ventilatory equivalents at ventilatory threshold, $\dot{V}D/\dot{V}T$ peak, $AaDO_2$ peak, and $PaCO_{2peak}$, as well as decreased ventilatory reserve and PaO_{2peak}. No difference was observed in the dyspnea score between the two groups, suggesting the mechanism by which exercise capacity impairment might be related to pulmonary changes, independent of the perception of respiratory fatigue.[55]

Exercise capacity was reduced in 71% of 35 patients with PLCH evaluated by means of an incremental treadmill CPET. In the majority, exercise limitation was multifactorial, and the most prevalent mechanisms included ventilatory, cardiocirculatory, and signs of limitation due to pulmonary hypertension, which was detected in 40% of subjects.[56]

Pulmonary Hypertension

In advanced PLCH, pulmonary hypertension (PH) is a complication that leads to an increase in mortality. In a high percentage of patients referred for lung transplantation, severe precapillary pulmonary hypertension has been detected.[57,58] However, in a large prospective cohort, only a small minority developed PH early in the course of PLCH.[11]

PH related to PLCH is included in group 5 of the PH clinical classification. Chronic hypoxemia, abnormal pulmonary mechanics, and vascular remodeling are the likely underlying pathophysiologic mechanisms. Proliferative vasculopathy involving muscular arteries and frequent venular involvement, with aspects of veno-occlusive disease, has been observed in biopsies of subjects with end-stage disease.[59] The severity of PH is not related to pulmonary function values; in a subgroup of patients, it progressed without obvious change in the lung parenchyma, consistent with an intrinsic pulmonary vascular disease.[59]

ROLE OF BRONCHOSCOPY

Bronchoscopy is grossly normal or shows smoking-related inflammation. Bronchial mucosa biopsy specimens are not useful for the diagnosis of PLCH but are helpful to exclude alternative diagnoses in atypical cases. Bronchoalveolar lavage (BAL) is rarely diagnostic of PLCH but provides additional information; a marked predominance of alveolar macrophages reflects tobacco use.[6] Alveolar cell counts may be normal in patients who ceased smoking for more than 6 months. A moderate increase of BAL eosinophils (usually <10%) may be present. An increased percentage of CD1a+ cells (>5%) is highly suggestive of PLCH, but the finding has a low sensitivity.[6,54] An increase in the proportion of alveolar lymphocytes should make one consider an alternative diagnosis. In patients with constitutional symptoms, BAL can exclude lung infection.

Transbronchial lung biopsies may be diagnostic for PLCH in expert centers, but they have variable diagnostic yields (15%–40%) due to the focal nature of histologic lesions.[6] Multiple specimens should be obtained and examined extensively using immunohistochemical techniques.

DIAGNOSIS

Definitive diagnosis of PLCH is made with histologic confirmation. It may be obtained through transbronchial lung biopsies or, most commonly, by surgical lung biopsy that, ideally, should be taken from nodular areas on lung HRCT. Since the lesions are focal, the specimens should be sufficiently large to ensure the availability of adequate material, and an extensive search for specific lesions should be performed using CD1a/CD207 immunostaining. In some cases, the predominant features may be suggestive of RB-ILD or desquamative interstitial pneumonia, but underlying specific LCH granulomas should be sought by comprehensive examination of biopsy samples, including immunohistochemistry. Correlations between CT features and pulmonary histopathology have shown that LCH granulomas may still be observed in patients with diffuse cystic disease, and that inflammatory cells (including LCH cells) may persist even inside thin-walled cysts.[6] In difficult cases, the presence of the *BRAF*^{V600E} mutation (and other MAPK alterations) helps confirm the diagnosis.

Lung HRCT has reduced the need for surgical lung biopsy. In a young adult smoker, the presence of a typical nodulocystic HRCT pattern allows for a presumptive diagnosis, along with close follow-up.[60] In case of surgical management of a pneumothorax, a lung biopsy may be performed during the same procedure. The biopsy of an associated bone or skin lesion allows for confirmation of the diagnosis in a patient with consistent pulmonary features. The indication for lung biopsy is determined in each patient, according to the evaluation of risks and potential benefits of the procedure. The differential diagnosis of other cystic diffuse lung diseases is guided by the clinical context and lung HRCT findings.[7,61]

INITIAL EVALUATION

At the time of diagnosis of PLCH, a thorough history and a comprehensive physical examination are essential to search for extrapulmonary LCH involvement. It is recommended that a skeletal radiograph survey be performed. However, if patients are meticulously and clinically evaluated for the absence of extra-thoracic LCH manifestations, the systematic search for bone involvement is less essential.[18]

A complete blood count and blood chemistry analysis (including total protein, electrolyte, creatinine, and liver and inflammation tests) should be systematically performed. They can rarely reveal LCH-related abnormalities (e.g., cholestasis in liver LCH involvement) and are useful for distinguishing alternative diagnoses or for patient therapeutic management. Morning urine osmolality is a screening test for suspected diabetes insipidus.[60]

Pulmonary function evaluation (including spirometry, plethysmography, and DL_{CO} determination) is essential to determine the degree of functional impairment and search for complications (e.g., COPD or pulmonary hypertension).

NATURAL HISTORY

The natural history of PLCH is unpredictable. In some patients, disease may resolve or stabilize after smoking cessation.[6,54] Other patients may develop progressive lung disease, often associated with evidence of airflow limitation and pulmonary vascular dysfunction.[60] Due to the inability to accurately predict the natural history, it is important that all patients undergo longitudinal follow-up. In a recent, large prospective study, most severe respiratory complications (chronic respiratory failure and/or pulmonary hypertension) occurred within the first 5 years after diagnosis.[11]

About 50% of patients experience a decrease of pulmonary function at 5 years of follow-up, and some will develop airflow obstruction.[62] In a 2-year prospective study, up to 20% of patients experienced a significant decline in their FEV_1.[52] A minority developed respiratory failure, with or without pulmonary hypertension, that was associated with decreased survival.[6,59] Besides the known association of LCH with various solid and hematologic tumors, PLCH patients are particularly at risk of lung carcinomas.[6,11] In contrast to what was reported two decades ago in two retrospective studies, the long-term survival of PLCH appears currently more favorable (>90% at 10 years).[11] Older age and decreased FEV_1 at the time of diagnosis are associated with increased mortality.[11] Conversely, BRAF status does not influence the risk of PLCH progression.[8] In some patients, despite regression of the disease, pulmonary function continues to deteriorate as a result of smoking-related COPD.[60] In addition, these patients are at risk for cardiovascular complications.[11]

Pregnancy does not appear to modify the course of PLCH, but certain precautions are required in women with diffuse cystic lesions and impaired pulmonary function due to the risk of pneumothorax during labor. Cases of exacerbation of diabetes insipidus have been reported during pregnancy, and de novo diabetes insipidus may also be observed after delivery.

Patient follow-up is based on physical examination, standard chest radiography, and lung function tests, typically performed every 3–6 months for the first 2 years, and then annually for at least 5 years in the absence of clinical progression of the disease.[6,11] Long-term follow-up may detect respiratory dysfunction or a rare relapse with recurrent nodule formation. Serial lung HRCT is recommended in patients who exhibit changes in their clinical, functional, or chest radiographic findings during follow-up.[52] In case of unexplained dyspnea or significant decrease in $D_{L_{CO}}$, Doppler echocardiography is indicated to search for pulmonary hypertension, which needs to be confirmed by cardiac catheterization.

MANAGEMENT

Management of patients with PLCH is tailored to the intensity of respiratory symptoms, the degree of impairment of lung function, and the progression of the disease. In all cases, smoking cessation is essential.[60] Smoking cessation for at least 6 months is associated with reduced longitudinal lung function decline.[52] It is the only intervention necessary in a substantial proportion of patients,[54] and individualized smoking cessation strategies should be used to address this powerful addictive behavior. Partial or complete resolution of lung HRCT abnormalities may occur without treatment, particularly after smoking cessation[60,63,64] (Fig. 59-6).

Combined inhaled corticosteroid and long-acting β_2-agonist therapy may provide benefit to patients with wheezing and moderate (reactive) obstructive lung disease.[60] Pneumothorax management may be particularly difficult. It recurs in half of the patients and often requires surgical pleurodesis.[65] Pleurectomy should ideally be avoided in these young patients who may be candidates for lung transplantation in the future. Lower respiratory tract infection is a common cause of deterioration for PLCH and should be promptly treated. An annual vaccination against influenza and a pneumococcal vaccine are recommended for patients with impaired lung function.

There is no general consensus regarding the role of immunosuppression or chemotherapy in management. Selected patients may experience improvement in lung function with therapy. Systemic corticosteroids have been used empirically without any evidence of efficacy.[6] Vinblastine, the cornerstone treatment of pediatric LCH,[5] has limited efficacy in adult PLCH.[66] Cladribine (2-chlorodeoxyadenosine), a purine nucleoside analogue directly toxic for lymphocyte, monocyte, and dendritic cells, is used as a second-line treatment in multisystem LCH.[67,68] It has been reported to induce remission or improve lung disease in selected PLCH cases.[60,69] This treatment is highly immunosuppressive (inducing prolonged lymphopenia), so prophylaxis for *Pneumocystis jirovecii* and herpes viruses should also be given. The efficacy and tolerance of cladribine for symptomatic forms of PLCH with impaired pulmonary function is being evaluated in a phase 2 clinical trial (Clinicaltrials.gov identifier NCT01473797).

Determination of *BRAF*^{V600E} or other mutations may assist with the development of an individualized therapeutic approach in patients with refractory disease,[3] but the role of MAPK targeted therapy in PLCH needs to be further assessed. A patient with progressive PLCH unresponsive to cladribine, whose lesion harbored a *MAP2K1* deletion, was reported to respond to the MEK inhibitor trametinib.[70]

Symptomatic treatments are useful for patients with respiratory failure and or pulmonary hypertension. Patients with PLCH who develop pulmonary hypertension have a particularly poor prognosis, and early referral for lung transplantation assessment is recommended. The role of vasodilator therapy in severe PLCH/pulmonary hypertension is not well established and should be reserved for expert centers because of the risk of worsening blood gas exchange.[59] Patients with advanced PLCH benefit from lung transplantation, with similar outcomes to patients with other diffuse infiltrative lung diseases, although PLCH may relapse in the transplanted lungs.[57,58,71]

CHAPTER 60

Pulmonary Lymphangioleiomyomatosis

Arnold S. Kristof
Joel Moss

Lymphangioleiomyomatosis (LAM) is a multisystem disorder, predominantly affecting women, that is characterized by cystic lung lesions, abdominal angiomyolipomas (AMLs), and lymphatic abnormalities. These pathologic features are caused by the proliferation of a neoplastic smooth muscle–like LAM cell that also has characteristics of immature melanocytes.[1] Inherited and sporadic forms of LAM have been described. Sporadic LAM is caused by somatic mutations primarily of the *tuberous sclerosis complex* (TSC) 2 (*TSC2*) gene, presumably occurring in a “cell of origin.”[2–4] Single cell sequencing of LAM lung lesions suggest that LAM cells may arise in the uterus.[5] LAM can also occur in about one-third of patients with TSC, an autosomal-dominant disorder that occurs in 1 of 6000 live births, and results from germline mutations in the *TSC1* or *TSC2* genes leading to widespread hamartomatous tumors in several organs including the brain, heart, skin, kidney, eyes, lung, and liver.[6–8]

EPIDEMIOLOGY

Until the establishment of LAM registries and the subsequent introduction of treatment with inhibitors of mechanistic target of rapamycin (mTOR),[9,10] LAM was considered to be a fatal disease of women of child-bearing age for which oophorectomy, antiestrogen therapy, and lung transplantation were the only available therapeutic options.[11] LAM is now best characterized as a chronic disease of post- and premenopausal women with an average life expectancy spanning 29 years from diagnosis.[10] Sporadic LAM is a rare disease with an estimated prevalence of 4.9 in 1,000,000 women.[12] LAM can also be detected in 30% to 40% of females patients with TSC, with the frequency increasing with age. Next-generation sequencing studies commonly indicate mosaic mutations in the *TSC1* or *TSC2* gene in patients with TSC who have no mutation identified (NMI) on analysis of a blood sample,[13,14] but mosaic *TSC2* mutations are only rarely found in patients diagnosed with the sporadic form of LAM.[15] Case series have identified LAM-like cystic lung disease in male patients with TSC, but clinically significant disease appears much less frequently in men than in women.[16,17]

CLINICAL PRESENTATION

Patients with LAM often present with a history of progressive dyspnea (Table 60-1).[9,18] Pneumothorax may cause acute onset pleuritic chest pain, is often recurrent, and occurs in up to 56% of patients on initial presentation.[19] The size of the lung cysts, as seen on high-resolution computed tomography (HRCT) scans (Fig. 60-1A) appears to be proportional to the incidence of pneumothorax.[20] Patients may also report cough, wheezing, or hemoptysis (Table 60-1). Other modes of presentation can include symptoms related to lymphatic involvement, such as lymphangioleiomyomas, which when present occur in the posterior mediastinum, retroperitoneum, or pelvis. The lymphatic involvement may also manifest as lymphadenopathy, chylothorax, chylous ascites, chyluria, or chyloptysis (Table 60-1).[9,21,22] Abdominal lymphangioleiomyomas were observed in 29% of patients with sporadic LAM, and in 9% of patients with TSC-LAM.[23] Angiomyolipomas (AML) are benign tumors usually localized in the kidneys and found in approximately 90% of patients with TSC-LAM (usually bilateral in patients with TSC) and in 30% of those with sporadic LAM (Table 60-1). AML may be identified on presentation and can spontaneously rupture and cause life-threatening hemorrhage.

The physical examination of LAM patients may disclose wheezing in 30% of patients, with a bronchodilator-responsive asthma-like presentation. In patients with TSC, typical skin lesions (e.g., angiofibroma, Fig. 60-2), or signs of neurologic impairment from brain involvement (e.g., cortical tubers, subependymal giant astrocytoma [SEGA]), may be evident.[24]

PATHOLOGY

Gross examination of lung sections shows cysts ranging in size from 0.2 to 2 cm.[1,25] Microscopically, proliferating LAM cells are found in the walls of cysts and can be found in association with narrowed or obstructed blood vessels, lymphatics, and bronchioles (Fig. 60-1B1, B2).[1,25] Focal hemosiderosis may be present. LAM cells are organized in microscopic nodules (LAM nodules) and appear to grow in a haphazard, disorderly fashion.[1,25] Two types of LAM cells have been described. Small, spindle-shaped cells predominate in the center of the lung nodules; epithelioid cells with large cytoplasm predominate at the periphery.[1,25] Both cell types react with antibodies against smooth muscle–cell antigens

TABLE 60-1 Clinical and Physiologic Features of Patients with Sporadic LAM and TSC-LAM

Demographics	TSC-LAM	Sporadic LAM
Number of patients	34	196
Age of LAM diagnosis	39.0 ± 1.6	41.4 ± 0.7
Signs and symptoms		
Dyspnea	70.6%	73.5%
Pneumothorax	47.1%	56.9%
Wheezing	58.8%	44.4%
Cough	26.5%	31.6%
Hemoptysis	20.6%	32.1%
Pleural effusions	5.9%	23.5%
Lung function		
Airflow obstruction	37.5%	60.8%
Low diffusion capacity	38.2%	60.3%
Normal spirometry	53.1%	30.7%
Extrapulmonary LAM		
Number of patients	67	256
Renal angiomyolipoma	93%	32%
Hepatic angiomyolipomas	33%	2%
Lymphangioleiomyomas	9%	29%
Ascites	6%	10%

TSC-LAM, Lymphangioleiomyomatosis associated with Tuberous Sclerosis Complex.
Data from Ryu JH, Moss J, Beck GJ, et al. The NHLBI Lymphangioleiomyomatosis Registry, Characteristics of 230 Patients at Enrollment. Am J Respir Crit Care Med. 2006;173:105; Avila NA, Dwyer AJ, Rabel A, et al. Sporadic lymphangioleiomyomatosis and tuberous sclerosis complex with lymphangioleiomyomatosis, comparison of CT features. Radiology. 2007;242:277.

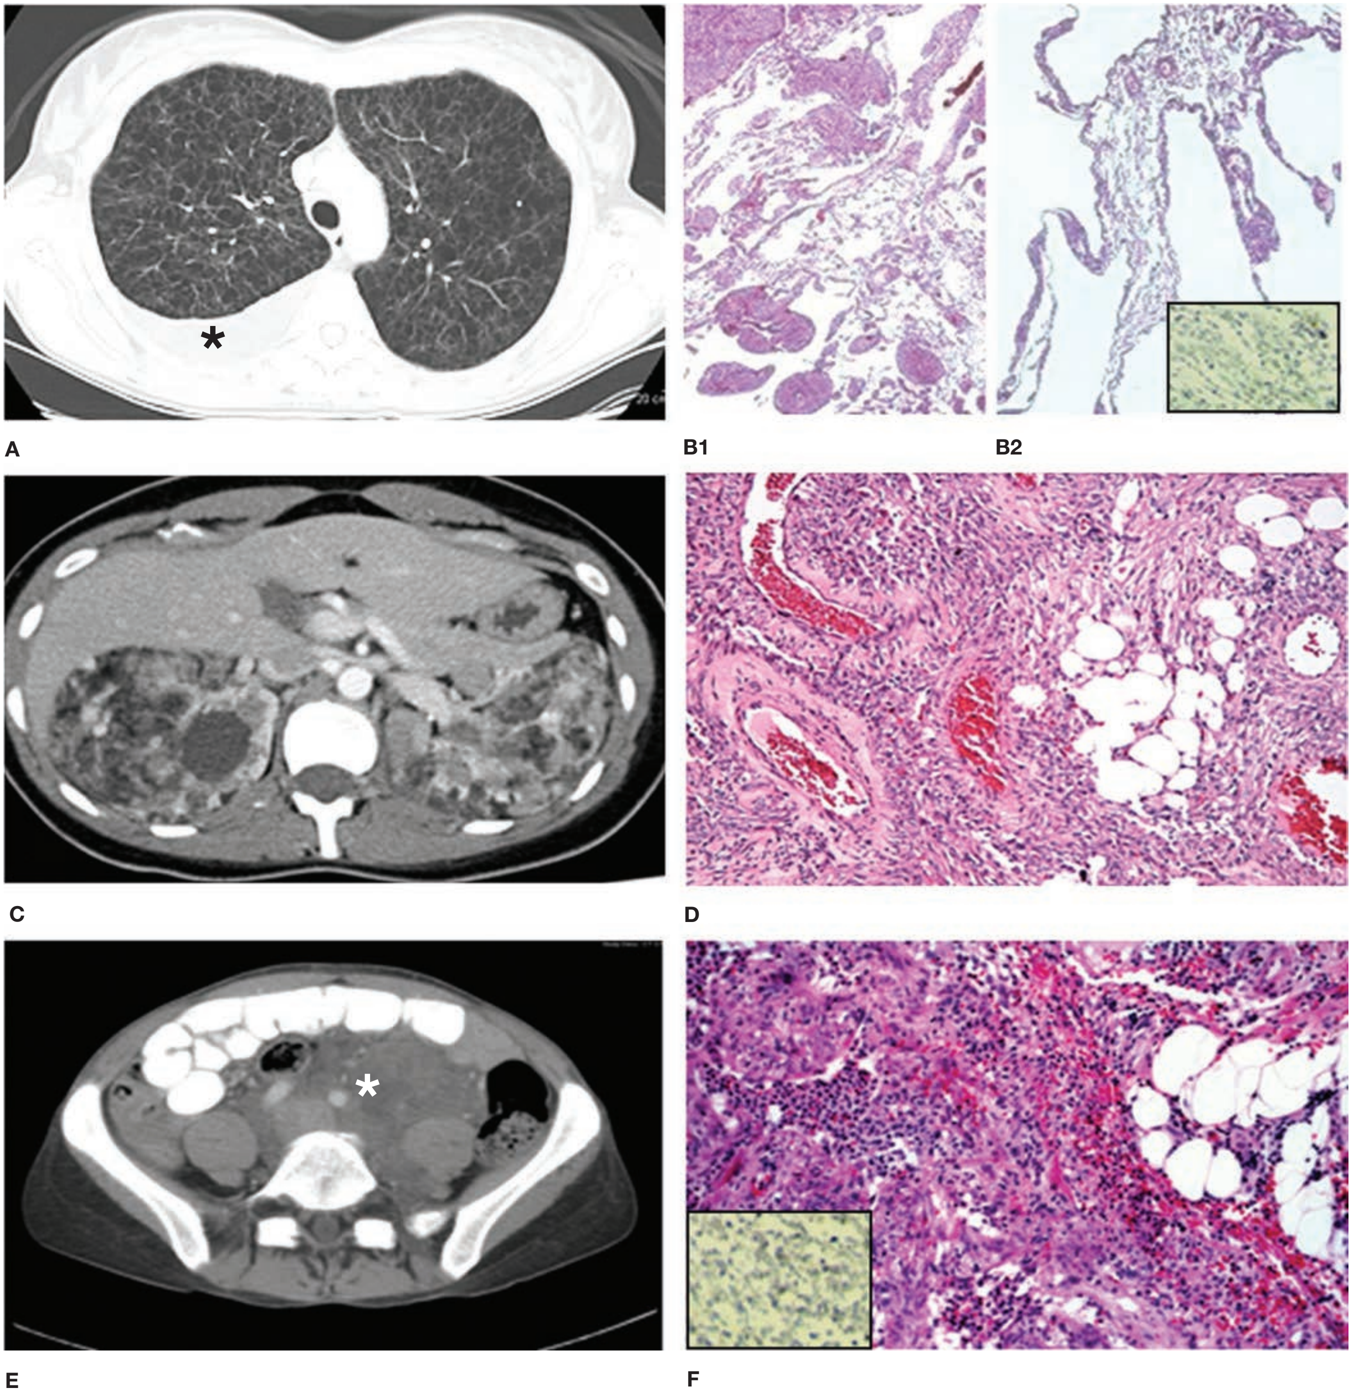

Figure 60-1 Computed tomography scans showing pulmonary and extrapulmonary images of patients with LAM, and the corresponding histopathologic findings. **A.** Multiple thin-walled cysts scattered throughout the lungs that have completely replaced the normal lung parenchyma. The *black asterisk* indicates the presence of a right pleural effusion. **B1** and **B2.** Histopathology of the lung showing characteristic nodular smooth muscle cell–like infiltrates and cystic lesions. Inset image on **B2** shows immunocytochemistry of lung tissue, showing reactivity with monoclonal antibody HMB45. **C.** Bilateral angiomyolipomas in a patient with TSC-LAM. The fatty, low-density component is clearly visualized. **D.** Histopathology of AML showing smooth muscle cell–like infiltrates, fatty tissue, and poorly differentiated vascular structures. **E.** Large, fluid-filled lymphangioleiomyoma *(white asterisk)* surrounding vascular structures. **F.** Histologic appearance of a lymphangioleiomyoma showing smooth muscle–like cells arranged in fascicular, trabecular or papillary patterns. Inset image on **F** shows immunocytochemistry of lymphangioleiomyoma tissue showing reactivity with monoclonal antibody HMB45.

(e.g., smooth muscle α-actin, vimentin). The epithelioid cells also react with human melanoma black 45 antibody (HMB-45), a monoclonal antibody that recognizes gp100, a premelanosomal protein encoded by the *Pmel17* gene (Fig. 60-1B2, inset).[1,25] Another antibody, αPEP13h, recognized the same protein, but identified a higher number (up to 85%) of cells in the LAM nodules.[26] Spindle-shaped LAM cells react with proliferating cell nuclear antigen (PCNA), indicating their high proliferative capacity.[1] Estrogen, progesterone, insulin-like growth factor, hyaluronic acid (CD44), and G protein–coupled receptors (e.g., chemokines, erythropoietin, prostaglandin, urotensin, angiotensin II) were demonstrated in LAM cells.[27–34]

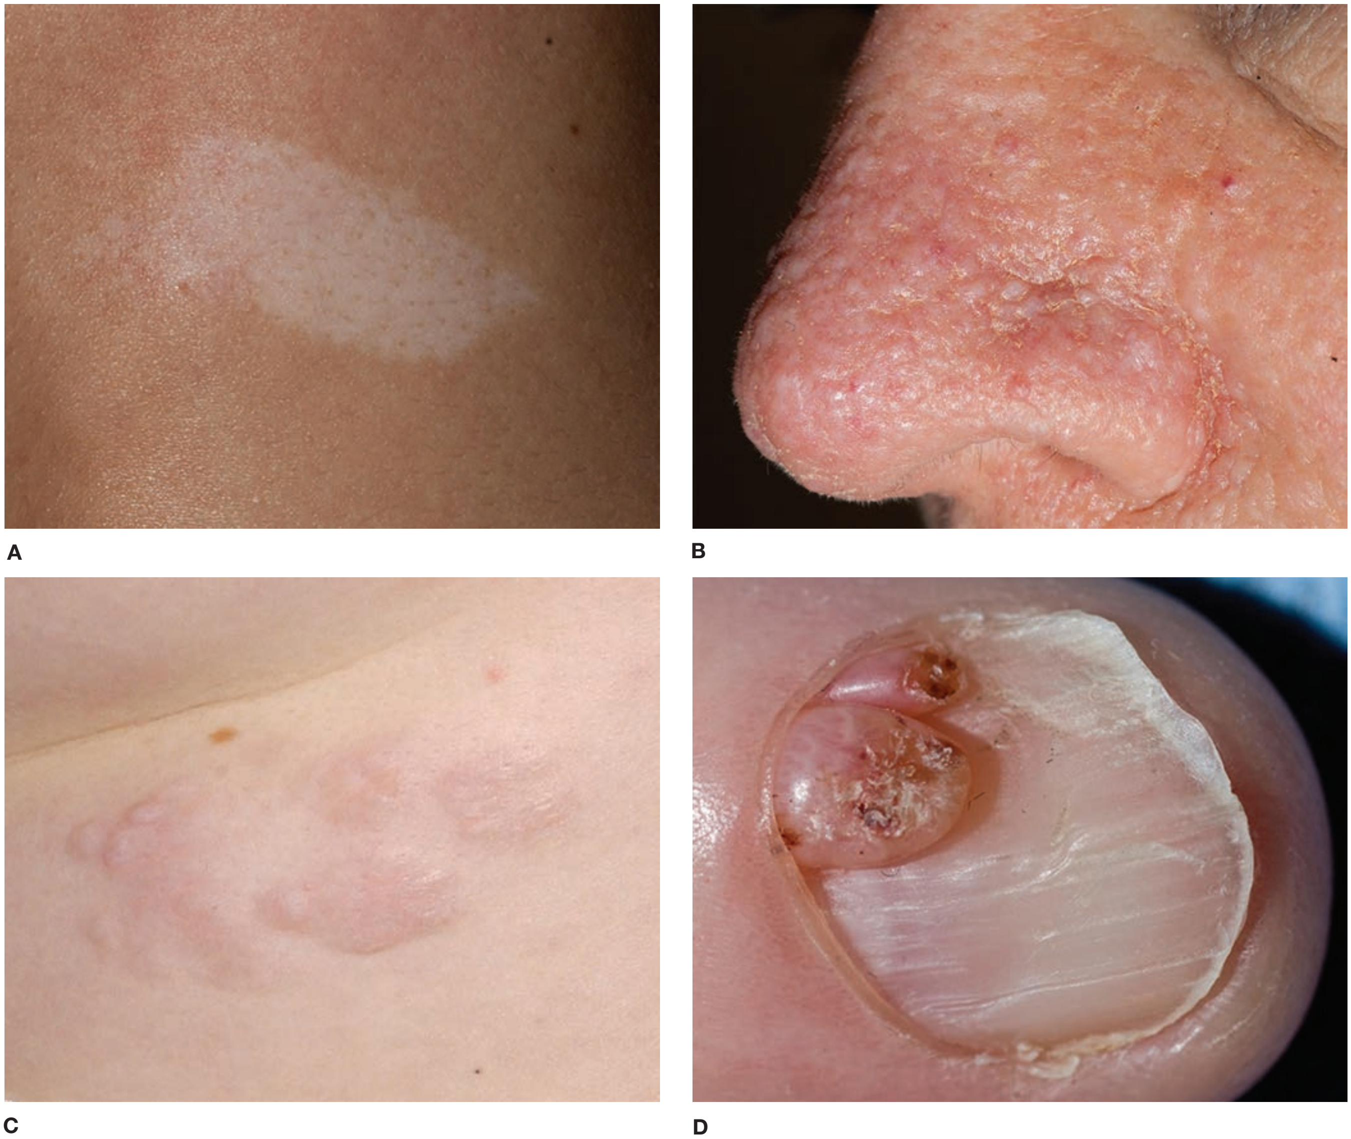

Figure 60-2 Skin manifestations of TSC in an adult woman. **A.** Large hypomelanotic macule on the back. **B.** Multiple facial angiofibromas involving the nose and adjacent cheek. **C.** Shagreen patch on the lower back. **D.** Periungual fibroma near the toenail.

AMLs are highly vascular tumors (Fig. 60-1C) comprising smooth muscle–like cells, immature, poorly differentiated blood vessels, and adipose tissue (Fig. 60-1D).[1,25] Tumors vary in size from 1 mm to more than 15 cm in diameter.[21,25] Smooth muscle–like cells found in AMLs have the same immunocytochemical properties as lung LAM cells (Fig. 60-1D).[1,25] Each of the major cell types in AML (vascular [angio], smooth muscle [myo], fat [lipoma]) may have mutations in the *TSC* genes.[2,3,35] The blood supply of AMLs originates from the renal arteries or aberrant vessels, which may completely disrupt normal kidney architecture.[21,25]

Other extrapulmonary abnormalities may include infiltration of intra-abdominal or retroperitoneal lymph nodes with smooth muscle cells, which correlate with the abdominal lymphadenopathy, as well as thoracic duct thickening and dilatation observed on imaging.[21,22,25] Lymphangioleiomyomas (Fig. 60-1E) are encapsulated lymphatic masses or chyle-filled cysts of varying sizes, composed of LAM cells arranged in fascicular, trabecular, or papillary patterns and associated with slit-like vascular channels (Fig. 60-1F).[1,22] Lymphatic vessels may be obstructed by LAM cells infiltrating their walls, resulting in the formation of tumor-like structures.

PATHOGENESIS

LAM is caused by proliferation of neoplastic LAM cells that have somatic mutations or deletions in the *TSC2* (16p13) gene, with less frequent involvement of the *TSC1* gene.[2,3,36] Consistent with Knudson's "two-hit" hypothesis of tumor development,[37] loss of heterozygosity of *TSC2* has been reported in LAM cells isolated from lung, blood, chyle, urine, and AML from both sporadic LAM and TSC-LAM patients. The presence of LAM cells in the blood, as well as the detection of identical mutations in AMLs and lung lesions from the same patients, suggested metastasis from an unknown source.[2,10,38,39] Further supporting this, LAM cells from patients receiving lung transplantation have been detected in the donor lung.[40,41] LAM cell clusters, consisting of LAM cell aggregates covered by lymphatic endothelial cells, have also been identified in chylous fluid.[42] Potential sources of lung LAM cells include AML, the lymphatic system, and the uterus.[5,43] The latter is supported by single cell sequencing analysis of pulmonary LAM nodules showing markers of uterine lineage.[5] Although the variable distribution and severity of LAM tumors suggest that LAM might be a genetic mosaic form of TSC, the detection of *TSC* genomic mutations in sporadic LAM by next-generation sequencing of blood DNA is rare.[44] It remains possible, however, that the somatic *TSC2* genomic mutations detected in LAM cells arose late in embryonic development or during postnatal development, thereby explaining the spectrum of disease.[44] Finally, a recent genome-wide association study identified a genomic variant in patients with LAM related to increased expression of an orphan nuclear receptor: *NR2F2*.[45] Its expression was also detected in LAM cells interrogated in a single cell sequencing study of LAM tumors from patient biopsies.[5]

A role for estrogens in the pathogenesis of LAM has been suggested, given the high prevalence in premenopausal women, and worsening of lung disease during pregnancy or following the administration of estrogens.[46–48] Single cell gene analysis and immunohistochemistry indicate elevated expression of female sex hormone receptors in lung and AML LAM cells.[5,27–29] Estrogens promote the proliferation of *TSC2*-null rat ELT3 leiomyosarcoma–derived cells in vitro, as well as the growth of subcutaneous tumors in a nude mouse xenograft system.[49] Estrogens also stimulate the growth of human AML-derived *TSC2*$^{-/-}$ cells, and increase matrix metalloproteinase (MMP-2) activity in LAM lung-derived cells, indicating an enhancing effect on cell invasiveness.[50–52]

The mechanism by which interstitial LAM cell proliferation causes lung cyst formation is unknown.[53] It has been proposed that compression of the airways by LAM cells leads to distention of the terminal airspaces and cyst formation.[1,25] It has also been proposed that degradation of lung elastic fibers is a major cause of the cystic lesions.[53,54] Matrix metalloproteinases (MMPs), which play a role in lung remodeling and lymphangiogenesis, are associated with LAM lesions.[55] LAM nodules contain MMP2, MMP9, MMP1, and MMP activators (MT1-MMP), as well as their inhibitors (TIMPs).[56,57] Levels of TIMP-3, which inhibits some MMP, were reportedly reduced in LAM lesions.[58,59] Compared with normal subjects, serum levels of MMP-9 were higher in patients with LAM,[60] suggesting that an imbalance between MMP and their inhibitors may contribute to lung destruction. Growth of *TSC2*-null lesions in mice was associated with an increase in MMP activity and vascular endothelial growth factor D (VEGF-D).[61] Degraded elastic fibers were demonstrated in the lung interstitium of mice with *TSC2*-null lesions,[61] and human lung LAM nodules show disrupted elastic fibers.[54] The presence of lymphatic spaces in the LAM nodules and strong immunoreactivity toward markers of lymphatic endothelial cells, including vascular endothelium growth factor C (VEGF-C), VEGF-D, vascular endothelium growth factor receptor (VEGFR) 3, and podoplanin, led to the hypothesis that disorganized lymphangiogenesis enhances metalloproteinase expression and lung remodeling.[61] Some combination of these mechanisms may be the best explanation for the pathogenesis of cystic lung destruction.

PULMONARY PHYSIOLOGY

Airflow obstruction is present in approximately 61% of patients with sporadic LAM,[9,62] with normal spirometry in about 31% and restrictive disease in the remainder. Lung disease appears to be milder in patients with TSC-LAM, with reduced frequency of obstructive or restrictive abnormality, and reduced decline in lung function over time (Table 60-1).[9,10,63,64] The cause of airflow limitation in LAM has been attributed to alveolar destruction,[65] but a study of pulmonary mechanics showed that lung elastic recoil was not significantly reduced.[66] Instead, increased upstream airway resistance was implicated as the major cause of airflow obstruction.[66,67] Reduced diffusing capacity (D_{LCO}) is present in approximately 60% of sporadic LAM patients.[9] Most patients have both decreased FEV_1 and D_{LCO}, but some patients have only a reduced D_{LCO}.[62] Ventilation-perfusion scintigraphy demonstrates reduced ventilation and perfusion, as well as a speckling pattern, correlating with the extent of cystic destruction and severity of lung function abnormalities.[68] Gas exchange, especially during exercise, is often abnormal with excessive minute ventilation and reduced breathing reserve (Table 60-2).[67,69] The appropriate reduction in dead space to tidal volume ratio during exercise is often not observed, and alveolar–arterial oxygen difference (A-a/O_2) is often increased.[67] The primary determinants of exercise limitation in LAM, therefore, are airflow limitation, decreased breathing reserve, dynamic hyperinflation, and limitations in oxygen transfer and carbon dioxide clearance due to loss of alveolar capillary surface area.[67,69,70] Pulmonary hypertension during exercise may also contribute to increased dead space and reduced gas transfer.[71]

TABLE 60-2 Cardiopulmonary Exercise Abnormalities in LAM

Decreased $\dot{V}_{O_{2max}}$ (% predicted)	57 ± 5
Decreased maximum work rate (% predicted)	68 ± 6
Decreased maximum oxygen pulse (% predicted)	67 ± 5
Decreased breathing reserve at end exercise (%)	8.5 ± 4
Decreased Pa_{O_2} (mm Hg resting vs. end exercise)	70 ± 2 vs. 60 ± 4
Increased maximum $\dot{V}_D/\dot{V}_T$ (% predicted resting vs. end exercise)	34 ± 3 vs. 38 ± 3
Increased A-a O_2 gradient (mm Hg resting vs. end exercise)	26 ± 5 vs. 42 ± 6

$\dot{V}_{O_{2max}}$, peak oxygen uptake; Pa_{O_2}, arterial oxygen tension; $\dot{V}_E/\dot{V}_{CO_2}$, ventilatory equivalent for CO_2; AT, anaerobic threshold; $\dot{V}_D/\dot{V}_T$, dead space ventilation ratio; A-a O_2 gradient, alveolar arterial oxygen tension difference.

RADIOLOGY

Chest radiographs in LAM range from normal to showing a reticular or nodular irregular shadowing or, in advanced stages, severe cystic changes. CT demonstrates diffuse, well-defined, round, thin-walled cysts scattered throughout the lungs. More recent studies suggest that LAM cysts are more likely to be located in the middle regions of the lung.[72] Cysts vary in size from a few millimeters to up to 2 cm (Fig. 60-1A).[68,73] Additional findings are pleural effusions and parenchymal opacities caused by chylous congestion (Fig. 60-1A).

Correlation between the extent of the cystic parenchymal replacement, as measured by HRCT, and the severity of the disease, as determined by spirometry, D_{LCO}, or exercise performance, has been reported.[69,73–77] Computer analysis of HRCT can quantify the extent of cystic changes, represented as the "cyst score," which is the percentage of lung volume occupied by cysts, and which can be used as a biomarker of disease severity and response to therapy.[77–81] An ongoing concern regarding the use of HRCT is the cumulative radiation exposure to the patient from repeated examinations. LAM cysts can also be evaluated by ultra low-dose CTs that generate cyst scores and can visualize other changes in the lung parenchyma at radiation exposures equivalent to those of a chest x-ray, thus reducing risk to patients.[82] Small cysts may not be visualized by this procedure. However, newer Zoom technology magnifies the small cysts and may thereby increase the apparent cyst score. The small cysts seen by Zoom correlate better with the decline in D_{LCO} than with changes in FEV_1.[83] The Zoom technology also demonstrates that cysts seen in different lung diseases may differ in structure, and it detects abnormalities in areas adjacent to the cysts that may appear to be radiographically normal by conventional CT[76,77]; these emphysematous changes were also seen by histopathology.[76] ^{129}Xe MRI is a promising methodology to assess heterogeneity in cyst ventilation, which may be a marker of early disease or disease progression.[84] Low-field MRI uses oxygen as the contrast agent and is being developed as a method for following ventilation and perfusion.[85] The fact that MRI magnets are now smaller, and that oxygen is the contrast agent, increases the availability of this technique and reduces the cost of the equipment.

Abdominal CT, ultrasonography, and MRI studies may show renal AML, abdominal lymphadenopathy, lymphangioleiomyoma, ascites, and dilation of the thoracic duct.[21,86] AMLs occur primarily in the kidney; far less commonly they can be found in the liver.[87] They are recognized by their characteristic appearance, consisting of areas of fatty density intermixed with more dense areas and normal-appearing renal parenchyma (Fig. 60-1C).[21] Atypical AMLs lacking adipose have been described; they exhibit a predominance of epithelioid LAM cells and, radiologically, may mimic renal cell carcinoma. Lymphangioleiomyomas appear as well-circumscribed masses of variable dimensions, comprising a wall and a central fluid-rich region (Fig. 60-1E).[21] Diurnal variation in size of lymphangioleiomyomas due to the effect of fasting, meals, or postural changes on chyle formation, has been demonstrated by CT and ultrasound. This feature may help differentiate them from malignant tumors and may explain worsening of symptoms during daytime.[88,89]

DIAGNOSIS

The diagnosis of LAM should be strongly suspected in any woman who presents with progressive dyspnea, recurrent pneumothorax, or extrapulmonary manifestations of LAM, in the presence of diffuse cystic lung disease.[9,22,90] The differential diagnosis includes pulmonary emphysema, Langerhans cell histiocytosis, Birt–Hogg–Dubé syndrome, and lymphocytic interstitial pneumonia. Guidelines for the diagnosis and management of LAM have been produced by the American Thoracic, Japanese Respiratory, and European Respiratory Societies.[91–93] In a patient with a compatible clinical history and a characteristic CT of the chest, definite LAM may be diagnosed in the presence of any of the following: (1) a sample of the lung, extrapulmonary lesions, or body fluid showing the histo- or cytopathologic features of LAM, (2) renal angiomyolipoma, (3) chylous effusion, (4) lymphangioleiomyoma, (5) elevated VEGF-D (levels >800 pg/mL), or (6) TSC.[92] Levels of serum VEGF-D, a lymphangiogenic factor, are increased in the serum of patients with LAM compared with normal individuals, and this is associated with lymphatic involvement.[94–97] A VEGF-D serum level greater than or equal to 800 pg/mL is unlikely to be found in other cystic lung diseases and appears to be diagnostic of LAM.[96,97] Transbronchial lung biopsy may yield adequate sample size for pathologic diagnosis and may obviate the need for surgical lung biopsy in patients for whom a noninvasive evaluation did not yield a definitive diagnosis.[98,99] In patients with probable LAM who can undergo close surveillance for progression of disease, pathologic confirmation may not be required unless the initiation of mTOR inhibitor therapy is being considered.[92]

PROGNOSIS

The clinical course of LAM is highly variable but more favorable than initially reported. The estimated median transplant-free survival time for LAM patients in the United States is 29 years from symptom onset and 23 years from diagnosis.[100] A recent study utilizing the National Institutes of Health LAM Registry estimated 10-year and 20-year transplant-free survival to be 85% and 64%, respectively. Lower FEV_1 or DL_{CO} at diagnosis was associated with reduced survival.[10] Hormonal status also affects survival, as decline in lung function slows after menopause.[10,62,101] Patients whose lung tissue shows predominance of cystic lesions tend to have worse lung function and prognosis than those with predominant LAM cell infiltrates.[102]

In patients who have had a lung biopsy, the severity of lung involvement in LAM may be assessed using the LAM Histology Score (LHS), which grades the extent of replacement of normal lung tissue by cystic lesions and LAM cell infiltrates.[103] The amount of tissue involvement is graded semiquantitatively based on percentage of lung tissue involved: LHS-1, <25%; LHS-2, 25% to 50%; and LHS-3, >50% lung tissue. LHS-2 and LHS-3 scores and the presence of hemosiderin-laden macrophages are associated with decreased survival.[103] Patients with predominant cystic disease are likely to have lower FEV_1 and DL_{CO}, lower peak oxygen uptake $\dot{V}_{O_2max}$, and more exercise-induced hypoxemia.[69,104]

As noted above, the severity of lung disease in LAM can also be graded by HRCT. HRCT findings correlate with pulmonary function tests, gas exchange, and exercise performance.[68,69,73–75] HRCT digital image analysis can quantify the percentage of lung volume affected by cysts (cyst score) and can evaluate the texture of areas not involved with cysts.[76,77] Using these methods, percentage of lung volume occupied by cysts was found to correlate with FEV_1, residual volume, and DL_{CO}.[76,77] A predominance of small cysts was associated with reduced DL_{CO} and less favorable clinical outcome.[83]

The simplest method of assessing the severity of lung disease in LAM is pulmonary function testing.[9,62] Most patients have airflow obstruction and impaired gas exchange. Early in the disease, a significant number of patients may have normal spirometry or only mild airflow obstruction, along with a marked decrease in diffusion capacity. In these patients, the severity of disease is best graded by tests of gas exchange such as $DL_{CO,}$ cardiopulmonary exercise testing, or 6-min walk test.[67,69,75] Exercise-induced hypoxemia can reduce exercise tolerance and may occur in the presence of near-normal DL_{CO} and FEV_1.[69] Correlation between $\dot{V}_{O_2max}$ and LHS scores, and between CT severity grade and A-a/O_2 gradient, dead space/tidal volume ratio, and $\dot{V}_{O_2max}$ have been demonstrated.[67,69,75–77] Rates of functional decline over time may help in defining the course of disease—that is, whether it is rapidly or slowly progressive. Sequential lung function testing every 3 to 6 months is warranted to assess the progression of disease.[62,101] A positive response to bronchodilators occurs in 25% to 30% of LAM patients.[104,105] Patients who respond to bronchodilators tend to have a predominantly cellular pattern of LAM lung lesions and greater rates of decline in FEV_1.[104] A low initial DL_{CO} was also reported to be a predictor of accelerated loss of FEV_1.[106]

Patients who present with exertional dyspnea and hemoptysis tend to have more severe disease, greater rates of disease progression, and lower survival than those who present with pneumothorax.[107] This may be due to either a delay in diagnosis or an insidious course in those who present with dyspnea. Lymphatic involvement (e.g., chylous effusions, lymphadenopathy, lymphangioleiomyomas) may be associated with a more severe form of LAM.[95,108,109] Correlation between LHS and the expression of VEGF-C has been reported.[109] Serum levels of VEGF-D are especially elevated in patients with lymphatic abnormalities, and they correlate inversely with DL_{CO} and directly with HRCT scan grading of severity of lung disease.[94,95,109] Measurement of serum VEGF-D may be of value in establishing a diagnosis, predicting rate of progression, and indicating response to therapy with sirolimus.[110,111]

GENERAL MANAGEMENT

LAM patients should be told about the chronic nature of LAM, and, if feasible, they should be referred to a specialized multidisciplinary LAM clinic and national patient support organization. In keeping with contemporary rehabilitation approaches for chronic lung disease,[112] patients should be encouraged to optimize their diet to achieve optimal body mass index and exercise regularly. The limits of exercise should be dictated only by their exercise capacity, as determined by their underlying lung function and any comorbidities. Sports involving extreme physical contact (e.g., martial arts) should be avoided if there is a risk of hemorrhage from AML. Patients should be advised to continue with normal activities, and that supplemental oxygen should be used during air travel if there is evidence of resting hypoxemia. The risk of life-threatening pneumothorax associated with air travel appears to be low.[113,114] However, if patients experience sudden onset of breathlessness or chest pain prior to air travel, pneumothorax should be excluded before departure. Finally, because of the risk, most clinicians would advise patients with severely compromised lung function to avoid flying, as a pneumothorax during flight could have serious consequences.

A 6-min walk test or a cardiopulmonary exercise test to uncover exercise-induced hypoxemia, and to determine the need for supplemental oxygen, is recommended. Patients who desaturate during exercise should be given supplemental oxygen at flow rates adjusted to sustain oxygen saturation above 88% to 90%. Patients should be advised against using estrogen-containing contraceptives and avoid phytoestrogen-rich food. For menopausal symptoms, compounds for the topical delivery of estrogens can improve quality of life and do not appear to cause a significant increase in serum levels.[115] Guidelines for patients with other estrogen-responsive tumors suggest that topical hormonal administration is likely safe, but a tailored discussion regarding the potential risk and benefits should be undertaken.[116]

TARGETED THERAPY

Currently the only recommended pharmacologic agents for treatment of LAM are the mTOR inhibitor sirolimus (rapamycin) and its analogues ("rapalogues").[91,117] Efforts to develop other therapeutics have adopted a drug-repurposing approach based on putative molecular targets that are dysregulated in LAM cells or nodules. Those that have undergone early clinical development are indicated in Table 60-3 and include antineoplastic and hormonal agents. Results from preclinical models suggest that statins, inhibitors of autophagy, tyrosine kinase inhibitors, and immune checkpoint inhibitors might be effective therapies. Established and putative therapeutic targets and drugs are discussed in the following section.

Mechanistic Target of Rapamycin (mTOR) Inhibitors

The discovery that the TSC genes *TSC1* and *TSC2* are involved in the pathogenesis of LAM led to major advances in its treatment. *TSC1* and *TSC2* are tumor suppressor genes that encode the proteins hamartin and tuberin, respectively. These proteins form a cytoplasmic complex in association with a third protein, TBC1D7, that regulates the intracellular serine/threonine kinase mTOR, which integrates growth factor, energy, and stress signaling, thereby regulating cell growth, proliferation, migration, and survival.[118–120] Two different complexes involving mTOR, mTORC1, and mTORC2, have been identified.[85–87] Tuberin is a GTPase-activating protein for the guanine nucleotide–binding protein RHEB (Ras homolog enriched in brain), promoting the formation of inactive RHEB-GDP from active RHEB-GTP.[85] Inhibition or absence of tuberin, as occurs with *TSC2* gene mutations, results in excessive mTORC1 activity, which results in inappropriate anabolic and tumorigenic effects.[121] Of note, mTOR (and its protein complexes) is a highly conserved eukaryotic protein that controls diverse cellular processes, including cellular growth, proliferation, differentiation, senescence, autophagy, and metabolism. Despite its pleiotropic effects, however, the striking effect of somatic *TSC2* loss on mTORC1 activity in LAM tumors[121] indicates its potential as a therapeutic target.

Rapamycin (Sirolimus) forms a complex with FK506-binding protein 12 and inhibits mTORC1.[120] Sirolimus provides only partial inhibition of mTORC1 and has some inhibitory effect on mTORC2 signaling.[122–124] In experimental models, sirolimus was shown to decrease tumor size in animals with a germline mutation of *TSC2*.[125] Treatment with a sirolimus analogue decreased the severity of renal cystadenomas and liver hemangiomas that spontaneously develop in *TSC2*$^{+/-}$ mice, and it decreased the growth of *TSC2*$^{-/-}$ tumors xenografted in nude mice.[126] In a rat model of spontaneous renal cell carcinoma associated with germline *TSC2* mutations, tumors exhibited excessive mTORC1 activation and proliferation, and these were reduced by administration of sirolimus.[125] In human subjects with TSC or LAM who had renal AMLs, treatment with sirolimus

TABLE 60-3 Targeted Therapies for LAM

Mechanism	Target	Drug	CT.gov Accession	Phase
Antineoplastic	mTORC1/2	Sirolimus	NCT00414648	3
		Everolimus	NCT01059318, NCT00792766	1/2
	mTORC2/RhoA	Simvastatin ± sirolimus	NCT02061397, NCT00001465	1, Observational[a]
	mTORC2/proteases	Doxycycline	NCT00989742	2
	GPCR signaling	Celecoxib	NCT02484664	1
	Tyrosine kinases			
	PDGFR	Nintedanib	NCT03062943	2
		Imatinib	NCT03131999	2
	Src	Saracatinib	NCT02116712	1
	Unknown	Resveratrol + sirolimus	NCT03253913	2
Autophagy	Autophagy initiation	Hydroxychloroquine + sirolimus	NCT01687179	1
Sex hormones	Aromatase	Letrazole	NCT01353209	2
	Progesterone receptor	Progesterone	NCT00001465	Observational[a]

[a] *Observational data suggesting lack of efficacy of simvastatin or progesterone in LAM are derived from the NIH LAM Natural History Study. These studies are discussed and cited in the text.*

decreased tumor size, but the tumors tended to increase in size after cessation of therapy.[127–130]

The effect of sirolimus on pulmonary function was examined in 89 patients with LAM in the MILES trial.[131] A total of 46 patients with significantly reduced lung function were treated with sirolimus and 43 with placebo for 12 months; both groups were followed for an additional year off of therapy. Compared with the placebo group, the sirolimus group experienced improvements in FVC, FEV_1, quality of life, and functional performance. Importantly, some subjects experienced decline in lung function despite therapy with sirolimus, and, in responders, decline in lung function tended to resume after cessation of therapy and paralleled that of the placebo group. In a post-hoc analysis, reduction in serum VEGF-D levels after administration of sirolimus appeared to correlate with improvement in lung function, suggesting that VEGF-D might be a useful biomarker of treatment response.[110,111] In another study, 19 patients with either rapidly progressive lung disease or lymphangioleiomyomas and chylous effusions were treated with sirolimus for approximately 2.5 years. Instead of the expected decline in lung function, an increase in FEV_1 and DL_{CO} was observed.[132] Nine patients experienced complete resolution of their chylous effusions and abdominal lymphangioleiomyomas.

Based on the findings in the MILES trial, it is recommended that sirolimus be given to patients whose FEV_1 has fallen below 70% or those above this threshold who are exhibiting an accelerated decline in lung function.[91] Sirolimus therapy is also recommended for LAM patients with symptomatic lymphangioleiomyomas and chylous pleural effusions or ascites. The accepted starting dose of sirolimus is 2 mg/d, and sirolimus serum levels should be monitored. Although the dose in the MILES trial was adjusted to attain trough levels between 5 and 15 ng/mL, retrospective analyses suggest that lower levels may suffice.[91] The role of low-dose (1 mg/d) sirolimus in preventing progression of disease in patients with mild disease is currently being investigated (MILED; NCT03150914). Adverse events associated with sirolimus therapy include oral mucosal ulcers, hypertension, hyperlipidemia, proteinuria, increased serum creatinine, infections, acne, amenorrhea, and sirolimus-related interstitial pneumonitis. Close patient monitoring is recommended. The durability and adverse effects of long-term sirolimus therapy are the subject of an ongoing registry-based study in patients with LAM (MIDAS; NCT02432560). In one long-term follow-up study, however, prolonged administration was associated with stabilization of lung function, as well as reduction in VEGF-D levels; in this case, there was no correlation between the magnitude of reduction in VEGF-D levels and the rate of decline in FEV_1.[133]

Antiestrogen Therapy

Oophorectomy, progesterone, and gonadotrophin-releasing hormone (GnRH) analogues have been employed in the treatment of LAM but are no longer routinely recommended.[91,93] Although antiestrogen therapies for LAM have not been studied in clinical trials, case reports and uncontrolled studies claimed a beneficial effect.[134] Subsequent studies challenged this assertion, however. An early study from Stanford and Mayo Clinic found little benefit in 19 patients after oophorectomy or treatment with progesterone.[135] In a retrospective analysis, a reduced rate of decline in FEV_1 and DL_{CO} was reported in premenopausal patients treated with progesterone.[101] However, when patients with short-term follow-up were excluded from the analysis, the effect of progesterone was not significant.[101] In another retrospective study, no difference was observed in disease progression between patients treated with or not treated with progesterone.[62] Data from studies that assessed the effect of GnRH analogues also have been inconclusive.[136,137] Current guidelines recommend against the use of hormonal therapy.[91] However, experimental data from preclinical models continue to indicate female hormone activity as a therapeutic target in LAM.[49–52,138,139] Further studies aimed at suppressing estrogen secretion (e.g., aromatase inhibitors) or activity are needed.

Matrix Metalloproteinase Inhibitors

Doxycycline is an MMP inhibitor that affects MMP production in *TSC2*-null ELT3 cells[140] and inhibits MMP2 secretion by *TSC2*-null mouse embryonic and human LAM cells.[141] A potential role of doxycycline in the treatment of LAM was suggested by a report of one patient with LAM in whom treatment with doxycycline decreased urinary MMP levels and improved lung function.[142] A decrease in serum and urine levels of MMP-9 and MMP-2 in 34 patients treated with doxycycline has been reported.[143] A controlled study showed that it is unlikely that doxycycline has a useful effect in LAM,[144] and current guidelines recommend against its use.[91]

Statins

There is evidence that both mTORC1 and mTORC2 are necessary for cell proliferation and survival in *TSC2*-deficient cells.[145] In the absence of tuberin, RhoA activity is increased, resulting in increased cell survival.[145] Since sirolimus primarily suppresses mTORC1 signaling, there is a rational for new therapies targeting mTORC2 signaling. Statins inhibit both sirolimus-sensitive and sirolimus-insensitive mechanisms of *TSC2*-null cell growth by inhibiting RhoA GTPase activity.[146] In one study, atorvastatin was shown to inhibit the growth of $TSC2^{-/-}$ rat ELT-3 cells and mouse embryonic fibroblasts while decreasing RHEB-GTPase activity and function.[146] A synergistic effect of simvastatin and sirolimus in inhibiting proliferation of *TSC2*-null cells and *TSC2*-null tumor growth has been described.[145] This effect appears to be specific for simvastatin; in a mouse model of TSC, atorvastatin failed to reduce the size of liver and renal tumors.[147] In a mouse model of LAM, simvastatin prevented alveolar space enlargement and, combined with sirolimus, blocked MMP upregulation, reducing *TSC2*-null lesions and alveolar destruction.[61] However, in a retrospective study of LAM patients, the rate of decline in lung diffusion capacity for patients who were treated with statins for hypercholesterolemia was greater than that of their matched off-statin controls.[148] In agreement, a phase 1 trial performed in 10 patients with LAM who were taking sirolimus indicated that the addition of simvastatin was well tolerated and lowered cholesterol but failed to improve lung function.[149]

Inhibitors of Autophagy

As a central regulator of energy, protein, and organellar homeostasis, autophagy is thought to play a major role in the molecular pathophysiology of neoplastic processes, including LAM.[150–152] mTORC1 is an endogenous suppressor of autophagy initiation; under conditions of cellular stress, mTORC1 activity is reduced, thereby triggering autophagy. mTOR inhibitors such as sirolimus therefore facilitate or increase autophagic activity, which, in LAM, may result in a paradoxical increase in cell survival.[151–154] Therefore, the autophagy inhibitor hydroxychloroquine may reverse this pro-survival effect of sirolimus, or as observed in other cancer cells, induce cell death and reduce proliferation.[152,154,155] The combination of mTORC1 inhibition with sirolimus and inhibition of autophagy with hydroxychloroquine was found to be more effective than either treatment alone in inhibiting the survival of *TSC2*-null cells and the growth of *TSC2*-null xenograft tumors, as well as the spontaneous development of renal tumors in $TSC2^{+/-}$ mice.[154] Inhibition of autophagy with hydroxychloroquine could potentially complement the effect of sirolimus in the treatment of LAM. In a phase 1 clinical trial, there was no toxicity associated with hydroxychloroquine when given in combination with sirolimus, and serum biomarkers of dose and change in lung function were identified.[156] These observations provide a rationale and potential tools for testing the effect of chloroquine and sirolimus in LAM patients.[157]

Checkpoint Inhibitors

As is the case for many neoplastic diseases, mechanisms in the tumor microenvironment that promote tumor growth and survival are emerging therapeutic targets.[158] In pulmonary LAM, these include angio- and lymphangiogenesis, cancer-associated fibroblasts, and the myeloid and lymphoid cells observed in LAM nodules.[159–162] Recent studies indicated increased infiltration of LAM nodules with T cells expressing programmed cell death 1 (PD1), a target for tumor-induced suppression of T-cell immunosurveillance; exogenously administered inhibitors of PD1 (i.e., "checkpoint inhibitors") reduced the growth of *TSC2*-deficient tumors in murine models.[163,164] In addition to checkpoint inhibitors, adoptively transferred T cells engineered to recognize LAM cell-specific antigens were effective in reducing the burden of *TSC2*-deficient tumors in mice.[165] Proof of efficacy of these approaches awaits further testing in clinical trials.

TREATMENT OF COMPLICATIONS

Several well-recognized complications of LAM are considered below.

Pneumothorax

Small pneumothoraces may be treated conservatively by chest tube drainage. Because of the high rate of pneumothorax recurrence, chemical or surgical pleurodesis by video-assisted thoracoscopy should be considered at the time of the initial event.[92,166] Chemical sclerosis, pleurectomy, mechanical abrasion, and talc poudrage are most effective, although high recurrence rates have been reported in some studies.[166] A recent report suggested that total pleural covering with surgical mesh might reduce recurrence rates.[167] In choosing the modality of pleurodesis, potential complications during future lung transplantation related to the degree of fibrothorax produced should be considered.[168,169] However, prior pleurodesis is not a contraindication to lung transplantation at experienced centers.

Chylous Effusions and Lymphangioleiomyomas

Chylous effusions may cause dyspnea and compromise respiratory function. Frequent drainage of chylous effusions may result in protein loss, lymphopenia, and weight loss.[132,170] Several treatments such as low-fat diet, pleuro-peritoneal or peritoneal-venous shunts, and thoracic duct embolization have been employed, but there is little experience with these therapeutic modalities in LAM.[171,172] The same is true of treatment with somatostatin and octreotide.[173] Lymphangioleiomyomas may cause abdominal pain, urinary frequency, obstipation, tenesmus, and peripheral edema. Abdominal symptoms and imaging associated with lymphangioleiomyomas may mimic malignancy and create diagnostic uncertainty.[89,174–176] Sirolimus is effective in facilitating resolution of chylous effusions and in decreasing the size of lymphangioleiomyomas and is therefore considered to be first line therapy for these complications. Invasive procedures should be reserved for symptomatic patients who fail medical therapy.[132,169]

Angiomyolipomas

AMLs less than 4 cm in diameter are usually well tolerated and are associated with preserved renal function.[87] The principal complication of larger AMLs is bleeding. Embolization, rather than resection, is recommended in the setting of acute hemorrhage to preserve kidney function.[177–180] Although rare, severe pain may also be an indication for selective embolization of the tumor. Prophylactic embolization may be undertaken in patients with large AMLs and no known episodes of bleeding, but strong evidence favoring this approach is lacking. In one case series with imaging follow-up, embolization led to a durable reduction in AML volume in patients with sporadic LAM; in contrast, initial response was observed in patients with TSC, but recurrence was often observed.[180] Since treatment with mTOR inhibitors (e.g., sirolimus, everolimus) reduces tumor size in about 44% to 50% of the patients, it may also prevent bleeding and the need for embolization or surgical intervention.[131,132,181] Of note, a therapeutic response to mTOR inhibitors may require dose escalation or the use of an alternative rapalog.[130,181,182] mTOR inhibitors may be effective in the treatment of large AMLs, although most prefer arterial embolization as a definitive initial approach.[127–129] Discontinuation of sirolimus therapy may result in enlargement of the AML, although they tend to be less than their original size.

Complications Associated with Pregnancy

Of the 353 pregnancies recorded in the LAM registry, 66.9% resulted in live birth, 16.7% had spontaneous abortion, and 15% had therapeutic abortion;[9] 22% of those who had been pregnant experienced worsening of respiratory symptoms during pregnancy. Patients who were diagnosed with LAM during pregnancy had more premature births and higher frequency of dyspnea, pneumothorax, and chylothorax than those diagnosed either before or after pregnancy.[183] A recent analysis of the UK and NHLBI LAM cohorts identified 16 patients with LAM who experienced pregnancy.[48] There was a higher than expected acceleration in lung function decline and rate of pneumothorax, but little in the way of obstetric complications. These data, along with anecdotal reports of worsening symptoms during pregnancy,[184] indicate that LAM patients should be counselled accordingly prior to conception. In patients with moderate to severe disease or those in whom lung function is declining rapidly, pregnancy should be discouraged. Patients with mild disease can be advised that although disease-related complications may occur, they will likely not impact significantly on the pregnancy or delivery with close medical and obstetrics monitoring. Sirolimus is a class C teratogen and inhibits wound healing. Although teratogenicity has not been observed in transplant patients on sirolimus therapy for immunosuppression who experience pregnancy and delivery, the long-term effects of fetal exposure are unknown.[169] Should a patient with moderate to severe LAM choose to continue sirolimus therapy during pregnancy, its short-term discontinuation during the peripartum period might prevent obstetric or surgical complications.

LUNG TRANSPLANTATION

We suggest that lung transplantation be considered when FEV_1 and D_{LCO} are less than 30% predicted, and/or the patient is on continuous supplemental oxygen and unable to carry out activities of daily living. Importantly, the patient should rate her quality of life as being poor, and should be certain that she wishes to undergo lung transplantation. In all, 138 LAM patients underwent lung transplantation in the United States between 2003 and 2017. This cohort was characterized by median FEV_1 of 23% predicted, median 6-min walk distance of 787 ft (240 m), and median oxygen requirement of 5 L. Median survival was estimated at 12 years and surpassed that of other chronic lung diseases.[185] There was no apparent effect of single vs. bilateral lung transplantation on outcome. The European experience is similar to that in the United States.[186] mTOR inhibitors impair wound healing, and their use in the immediate posttransplant period was associated with fatal dehiscence of the bronchial anastomosis. As a result, some have suggested that they be discontinued while patients are on the waiting list for transplantation. However, transplantation has been safely performed on patients who continued therapy until the immediate preoperative period, and an increasing number of centers now allow patients to remain on sirolimus while on the wait list. Reinitiation of sirolimus after healing of the bronchial anastomoses may be advised for the treatment of pre-existing extrapulmonary manifestations of LAM (AML, lymphangioleiomyoma) or for control of chylous pleural effusions.[40,41] Rarely, LAM can recur in the lung allograft, but since, to a large extent, this has not been associated with significant allograft dysfunction, routine inclusion of sirolimus in the post-transplant immunosuppressive regimen is not advised.

LAM IN TUBEROUS SCLEROSIS COMPLEX

TSC is a multisystem autosomal-dominant disorder that affects men and women equally. Its frequency is 1 in 12,000 to 14,000 children under the age of 10, or 1 in 6000 births.[187–189] It is characterized by neurodevelopmental syndromes (e.g., mental retardation, autism, seizures, cortical tubers) and tumors in multiple organs (e.g., facial angiofibroma, periungual fibromas, Shagreen patches, giant-cell astrocytomas, cardiac rhabdomyomas) (Fig. 60-2).[187] In addition to inherited heterozygous germline mutations, generalized and segmental mosaic forms of TSC have been documented.[188,189] The severity of disease appears to correlate with the location and extent of tissue affected by the mosaic mutation. It is therefore possible that sporadic LAM can be an extreme mosaic form of TSC. In fact, the association of TSC and cystic lung disease has long been reported in the literature.[190] Initially the prevalence of clinically significant LAM in TSC (TSC-LAM) was thought to be relatively low, ranging from 0.6% to 2.3% of TSC patients.[190–193] However, subsequent studies showed that the prevalence of lung cysts in women with LAM ranges from 26% to 38%.[6,194,195] Lung cysts were demonstrated in 13% of men with TSC, but only 3% of male patients had >10 cysts, indicating that the disease is generally mild if present.[16] In another case series, the prevalence of LAM in males with TSC, as determined by >4 cysts on CT, was as high as 38%, but the lung disease was mild.[17] The NHLBI LAM registry reported data from 34 TSC patients who were known to have LAM or were later confirmed to have LAM (Table 60-1).[9] Renal AML occurred in 93% of TSC-LAM patients and in only 32% of sporadic LAM subjects. Lymphangioleiomyomas and chylous effusions were more common in sporadic LAM. In a study comparing CT features of 67 patients with TSC-LAM and 256 patients with sporadic LAM, severe disease was present in 25% of TSC-LAM patients versus 40% of sporadic LAM patients.[23] Multifocal micronodular pneumocyte hyperplasia (MMPH) is another pulmonary manifestation of TSC that occurs in males and females; it is thought to be benign.[8] Sclerotic bone lesions were very common in patients with TSC-LAM.[196]

Perhaps because LAM is often diagnosed incidentally or by screening in young patients with TSC, its burden and progression are thought to be milder than in its sporadic form, which, in contrast, is most often diagnosed when patients are symptomatic. Nonetheless, LAM is the leading cause of death in women with TSC,[197] and TSC patients who initially present with symptoms tend to experience more severe lung disease; clinically significant LAM in men with TSC appears to be exceedingly rare. It is therefore recommended that women with TSC be screened for LAM at least once at the age of 18 with HRCT and pulmonary function testing.[198]
